## PREFACE TO THE FIRST EDITION

This book has been written in response to a demand for a treatise based upon modern progress in hygiene and sanitation. The work is planned to include those fields of the medical and related sciences which form the foundation of public health work. So far as I know, no other book on the subject covers the broad field considered in this volume. The progress in hygiene and sanitation has been so rapid that the subject of preventive medicine has become a specialty, and its scope has become so broad that the question throughout the making of this book has been rather what to leave out than what to include. The facts here brought together are widely scattered in the literature and many of them are difficult of access; they have been collected for the convenience of the student of medicine and the physician, as well as those engaged in sanitary engineering or public health work.

During twenty-three years of varied experience in public health work it has been my good fortune to have served as quarantine officer, in epidemic campaigns, in epidemiological investigations, and in public health laboratories, at home, on the Continent, and in the tropics. The fruits of these experiences are reflected in this book, which may be taken as representing my personal views gained in the field, in the laboratory, in the classroom, and in administrative offices.

It is well-nigh impossible to prevent or suppress a communicable disease without a knowledge of its mode of transmission. This is the most important single fact for successful personal prophylaxis, as well as in the general warfare against infection; therefore the communicable diseases have been grouped in accordance with their modes of transference. Each one of the important communicable diseases is discussed separately in order to bring out the salient points upon which prevention is based. The classification adopted is believed to be unique and should prove helpful to those who are especially concerned in the prevention of infection.

The book may be considered in two parts, namely, that which deals with the person (hygiene) and that which deals with the environment (sanitation). The first part includes the prevention of the communicable diseases, venereal prophylaxis, heredity, immunity, eugenics, and similar subjects. The second part deals with our environment in its relation to health and disease and includes a discussion of food, water, air, soil, disposal of wastes, vital statistics, diseases of occupation, industrial

hygiene, school hygiene, disinfection, quarantine, isolation, and other topics of sanitary importance, as well as subjects of interest to health officers. All the important methods used in public health laboratories are described.

To have made this book in monographic style with references to authorities for every statement would have resulted in an unwieldy work of impractical size and form. The textbook style has therefore been adopted and citation of authorities for facts that are now well established has been regarded as unnecessary. In this respect it may seem that I have given scant credit to many workers from whose writings I have borrowed results, thoughts, and sometimes words or even sentences. At the end of each chapter will be found a list of references to articles or books that I have especially drawn upon, and I desire to acknowledge my obligations to these sources as well as to refer the reader to them for further study of particular subjects. I have also drawn freely upon my own previous writings and those of my co-workers in compiling this book. The chapter on "Disinfection" is based upon my book entitled: "Disinfection and Disinfections," published by P. Blakiston's Sons & Co., Philadelphia, 1902.

I have received generous help from a number of friends and it is a pleasure here to acknowledge especially my obligation to Dr. David L. Edsall for reading and correcting the chapter on Diseases of Occupations, to Dr. John F. Anderson and Dr. Joseph Goldberger for revising the chapters upon Measles and Typhus Fever, to Prof. George C. Whipple for reading and improving the chapter upon Water, to Charles T. Brues for many suggestions in the section upon insect-borne diseases, and to Prof. W. E. Castle for a similar service with the section on Heredity. Dr. Charles Wardell Stiles has kindly furnished information concerning the relation of parasites to soil. I also desire to express my obligations to Prof. Arthur I. Kendall, Dr. Harold L. Amoss, Dr. Lewis W. Hackett, Prof. William D. Frost, and Miss Emily G. Philpotts.

It has been my object to give in this volume the scientific basis upon which the prevention of disease and the maintenance of health must rest. Exact knowledge has taken the place of fads and fancies in hygiene and sanitation; the capable health officer now possesses facts concerning infections which permit their prevention and even their suppression in some instances. Many of these problems are complicated with economic and social difficulties, which are given due consideration, for preventive medicine has become a basic factor in sociology.

M. J. ROSENAU

BOSTON

## PREFACE TO THE FOURTH EDITION

This edition has been largely rewritten and entirely reset. The following new subjects have been added: Public Health Methods and Measures; Relative Values in Public Health Work; A Public Health Program; Organization of Health Departments; Median Endemic Index; Housing; Rural Sanitation; Public Health Education; Public Health Nursing; Drug Addiction, Alcoholism; Undernutrition; Sanitary Surveys; Infant Mortality; Koch's Laws; Intelligence Quotient; Vitamins; Oral Hygiene; Ocular Hygiene; Personal Hygiene; and a Laboratory Course in Preventive Medicine and Hygiene.

The following diseases are discussed in this book for the first time: Vincent's Angina; Deer-Fly Fever; Leishmaniasis; Epidemic Encephalitis; Yaws; Psychoneuroses; War Edema.

The following subjects have been rewritten: Venereal Diseases and Hygiene of Sex; Dysentery; Influenza; Trench Fever; Mental Defectives; Food Poisoning; Botulism; Deficiency Diseases and Goiter. More or less extensive changes have been made throughout the rest of the volume.

I have received letters from many parts of the world calling my attention to errors of commission or omission. I am grateful for these suggestions and will appreciate others that may help improve the book and keep it up to date. Acknowledgment of special help is stated on page xi.

M. J. ROSENAU

HARVARD MEDICAL SCHOOL  
BOSTON

## ACKNOWLEDGMENTS

In making this book I have enjoyed assistance from many friends. I am especially indebted to the following for help in the subjects named:

DR. J. P. LEAKE, Smallpox and Vaccination  
DR. A. M. STIMSON, Rabies  
DR. W. A. HINTON, Glanders, The Wassermann Reaction  
DR. F. H. VERHOEFF, Preventable Blindness, Ocular Hygiene  
DR. A. W. SELLARDS, Dysentery  
DR. E. E. TYZZER, Leishmaniasis  
DR. A. K. KRAUSE, Tuberculosis  
DR. E. H. PLACE, Diphtheria, Scarlet Fever, Measles, Whooping Cough  
DR. RUFUS COLE, Pneumonia  
DR. C. W. STILES, Hookworm Disease  
DR. B. H. RANSOM, Intestinal Parasites  
DR. H. R. CARTER, Mosquitoes, Malaria  
DR. L. O. HOWARD, Flies  
DR. HARRY PLOTZ, Lice, Typhus Fever  
DR. G. W. MCCOY, Leprosy, Anthrax  
DR. R. H. CREEL, Maritime Quarantine  
DR. J. BRONFENBRENNER, Immunity  
DR. J. R. MOHLER, Meat Inspection  
DR. J. GOLDBERGER, Pellagra  
DR. C.-E. A. WINSLOW, Ventilation  
DR. ALICE HAMILTON, Industrial Hygiene  
DR. G. C. WHIPPLE, Sewage, Garbage and Refuse  
DR. J. W. TRASK, Vital Statistics  
DR. T. W. SALMON, Mental Hygiene

Lieutenant Colonel C. F. Foster, Major J. E. Bayliss, Major E. E. Hume and Major G. F. Lull read and corrected the chapter on Military Hygiene. My colleagues, Dr. M. J. Schlesinger, Dr. Harry Weiss, Dr. D. L. Sisco, Dr. Benjamin White, Mr. R. W. Lamson, and Mr. A. P. Pratt, helped me see the book through the press. My efficient secretary, Miss Mae C. Moran, made the index.

D. Appleton and Company have met with unusual difficulties in publishing a book of this size at this time, and I am indebted for their coöperation, especially that of Dr. J. R. Broome.

## SECTION I

### PREVENTION OF THE COMMUNICABLE DISEASES

CHAPTER	PAGE
I. DISEASES HAVING SPECIFIC OR SPECIAL PROPHYLACTIC MEASURES . . . . .	1
SMALLPOX AND VACCINATION	
Historical Note, 1; Vaccination, 3; Vaccine Virus, 4; Methods of Vaccination, 9; Indices of a Successful Vaccination, 12; The Immunity, 14; Revaccination, 18; Claims for Vaccination, 20; Vaccination of Exposed Persons, 20; Dangers and Complications, 21; The Government Control of Vaccine Virus, 24; The Unity of Cowpox and Smallpox, 25; Compulsory Vaccination, 25; Inoculation or Variola Inoculata, 26; Prevalence of Smallpox, 28; Epidemiology, 29; Modes of Infection, 30; Resistance of the Virus, 31; Smallpox in the Vaccinated and Unvaccinated, 31; Isolation and Disinfection, 35.	
RABIES:	
General considerations, 38; Period of Incubation, 39; Entrance and Exit of the Virus, 40; The Relative Danger of Bites, 41; Viability, 41; Prophylaxis, 42; The Local Treatment of the Wound, 43; The Pasteur Prophylactic Treatment, 44; Diagnosis of Rabies in Dogs, 51.	
VENEREAL DISEASES:	
Syphilis, 55; Gonorrhea, 67; Chaneroid, 72.	
VENEREAL PROPHYLAXIS AND HYGIENE OF SEX:	
Prevalence, 73; Attitude, 75; Education, 76; Notification, 78; Continence, 79; Personal Hygiene, 79; Alcohol, 80; Prostitution, 80; Segregation, 81; Medical Prophylaxis, 81; Hospitals and Clinics, 85.	
PREVENTABLE BLINDNESS:	
Ophthalmia Neonatorum, 87; Trachoma, 92; Toxic Amblyopia, 94; Accidents, 94.	
TETANUS:	
Etiology, 95; Occurrence, 97; Trismus Neonatorum, 99; Incubation, 100; Resistance, 100; Prophylaxis, 102.	
II. DISEASES SPREAD LARGELY THROUGH THE ALVINE DISCHARGES . . . . .	105
TYPHOID FEVER	
General Considerations, 105; Historical Landmarks, 106; Prevalence, 107; Channels of Entrance and Exit, 110; Diagnosis, 110; Bacillus Carriers, 113; Resistance of the Virus, 116; Typhoid Bacillus in Nature, 117; Modes of Spread, 118; Typhoid Vaccines, 128; Management of Case, 133; Personal Prophylaxis, 135.	
PARATYPHOID FEVER	
General Considerations, 136; Paratyphoid Fever and Food Poisoning, 138.	

## CHOLERA

General Considerations, 139; The Cause and Contributing Causes, 139; Diagnosis, 141; Modes of Transmission, 142; Bacillus Carriers, 144; Immunity and Prophylactic Inoculations, 145; Quarantine, 146; Personal Prophylaxis, 147.

## DYSENTERY

Bacillary Dysentery, 148; Amebic Dysentery, 150; Contrast between Bacillary and Amebic Dysentery, 151.

## HOOKWORM DISEASE

Distribution, 153; Species of Hookworm, 154; Modes of Transmission, 154; The Parasite, 154; Immunity, 157; Resistance of the Parasite, 157; Prevention, 158; Plan of Campaign, 160.

### III. DISEASES SPREAD LARGELY THROUGH DISCHARGES FROM THE MOUTH AND NOSE . . . . . 163

## TUBERCULOSIS

General Considerations, 163; The Difference between Human and Bovine Tubercle Bacilli, 165; Bovine Tuberculosis in Man, 166; Modes of Infection, 170; Immunity, 177; Resistance of the Virus, 180; Prevention, 181; Segregation—Sanatoria, 182; Personal Prophylaxis, 184; Tuberculosis in Children, 187; Bovine Tuberculosis, 188; Directions for Testing Cattle with Tuberculin, 188; The Bang Method of Suppressing Bovine Tuberculosis, 189; Organization of a Local Tuberculosis Campaign, 190; Outlook, 191.

## DIPHTHERIA

General Considerations, 191; Modes of Transmission, 193; Bacillus Carriers, 195; Diagnosis, 198; Resistance, 198; Immunity, 199; The Schick Reaction, 201; The Control of Outbreaks, 202; Responsibility of the Medical Profession, 206; Prevention of Post-diphtheritic Paralysis, 207; Prevention of Serum Sickness and Anaphylactic Shock, 208; Historical Note, 209.

### VINCENT'S ANGINA . . . . . 210

## MEASLES

General Considerations, 212; Immunity, 213; Resistance of the Virus, 214; Modes of Transmission, 215; Prevention, 217.

### GERMAN MEASLES . . . . . 219

## SCARLET FEVER

General Considerations, 219; Modes of Transmission, 220; Immunity, 223; Prophylaxis, 223.

## WHOOPIING-COUGH

General Considerations, 224; Modes of Transmission, 225; Immunity, 226; Prevention, 226; Mortality, 228.

### MUMPS . . . . . 228

## LOBAR PNEUMONIA

General Considerations, 230; Types of Pneumococci, 231; Resistance of the Virus, 232; Modes of Transmission, 232; Carriers, 233; Immunity, 234; Prevention, 236; Preventive Measures, 237.

## INFLUENZA

General Considerations, 239; Etiology, 241; Mode of Infection, 241; Epidemiology, 241; Vaccines, 244; Administrative Measures, 245.

## COMMON COLDS

General Considerations, 246; Prevention, 247; Drafts and Chilling, 248.

## CEREROSPINAL FEVER

General Considerations, 250; Epidemiology, 251; Modes of Transmission, 252; Carriers, 254; Prevention, 257.

## IV. INSECT-BORNE DISEASES . . . . . 259

### GENERAL CONSIDERATIONS . . . . . 259

#### INSECTICIDES

General Considerations, 266; Preparation of the Room for Fumigation, 266; The Relative Efficiency of Insecticides, 267; Sulphur, 269; Formaldehyd, 270; Pyrethrum, 271; Phenol-Campher, 272; Hydrocyanic Acid Gas, 273; Bisulphid of Carbon, 274; Petroleum, 275; Arsenic, 276.

#### MOSQUITOES

General Considerations, 279; Life History and Habits, 280; The Destruction of Mosquitoes, 281; Malaria, 286; Yellow Fever, 295; Dengue, 303; Filariasis, 305.

#### FLIES

General Considerations, 307; Life History of the Musca Domestica, 309; Life History of Stomoxys Calcitrans, 310; Flies as Mechanical Carriers of Infection, 311; Suppression, 315; Sleeping Sickness, 317; Deer-Fly Fever, 321; Pappataci Fever, 322.

#### FLEAS

General Considerations, 322; Pulicides, 325; Relation of Plague to Rats and Fleas, 325.

#### RATS AND OTHER RODENTS

General Considerations, 328; Breeding and Prevalence, 329; Migration, 330; On Vessels, 331; Food, 331; Habits, 332; Rat-Bite Fever, 332; Plague in Rats, 333; Acute Infectious Jaundice, 335; Rat Leprosy, 337; Trichinosis, 337; Food Infection, 337; Other Parasites, 337; Economic Importance, 338; Suppression of Rats, 338; Squirrels and Plague, 344; Plague, 345.

#### TICKS

General Considerations, 354; Texas Fever, 356; Rocky Mountain Spotted Fever, 356; Japanese River Fever, 361; Relapsing Fevers, 361.

#### LICE

General Considerations, 362; Lice Bites and the Transmission of Disease, 365; Delousing, 366; Lice as a Military Problem, 369; Typhus Fever, 370; Trench Fever, 376.

#### BEDBUGS

General Considerations, 378; Suppression, 379.

### LEISHMANIASIS . . . . . 380

### ROACHES . . . . . 383

## V. MISCELLANEOUS DISEASES . . . . . 386

### INFANTILE PARALYSIS

General Considerations, 386; Resistance of the Virus, 389; Immunity, 390; Modes of Transmission, 390; Prevention, 392.

### EPIDEMIC ENCEPHALITIS . . . . . 394

### CHICKENPOX . . . . . 395

#### GLANDERS

General Considerations, 396; Diagnosis, 397; Prevention, 400.

#### ANTHRAX

General Considerations, 401; Resistance, 402; Prevention, 402.

### FOOT-AND-MOUTH DISEASE . . . . . 405

PUBLIC HEALTH NURSING . . . . .	483
NUISANCES . . . . .	483
FACE MASKS . . . . .	485
DRUG ADDICTION . . . . .	486
ALCOHOL . . . . .	487
SANITARY SURVEYS . . . . .	493
MANAGEMENT OF AN EPIDEMIC CAMPAIGN . . . . .	495
QUARANTINE . . . . .	498
General Considerations, 498; Maritime Quarantine, 502; Quarantine Procedures, 509; The Bill of Health, 509; The Equipment of a Quarantine Station, 510; Qualifications of Quarantine Officers,	

511; Disinfection of Ships, 511; Fumigation of Ships, 513; Cargo, 518; Foreign Inspection Service, 518; National versus State Quarantine, 519; Interstate Quarantine, 519.

## SECTION IV

## IMMUNITY, HEREDITY, AND EUGENICS

I. IMMUNITY . . . . .	523
GENERAL CONSIDERATIONS . . . . .	523
Mechanism of Immunity, 527; Theories of Immunity, 528; Natural Immunity, 530; Acquired Immunity, 532; Non-Specific Immunity, 532; Mixed Immunity, 533; How Active Immunity May Be Acquired, 533; Bacterial Vaccines, 535; Specificity, 537; Local and General Immunity, 539; Bacillus Carriers, 540; Latency, 542; Lowered Resistance, 542; Relation between Host and Parasite, 546; Ehrlich's Side-Chain Theory of Immunity, 547; Antitoxic Immunity, 553.	
TOXINS . . . . .	553
ANTITOXINS	
General Considerations, 558; Preparation of Antitoxin, 561; Method of Concentrating Diphtheria Antitoxin, 562; Mode of Action, 563.	
ENDOTOXINS . . . . .	565
STANDARDIZATION OF ANTITOXIC SERA	
Standardization of Diphtheria Antitoxin, 566; Standardization of Tetanus Antitoxin, 568.	
PHAGOCYTOSIS . . . . .	570
OPSONINS . . . . .	574
LYSINS . . . . .	575
HEMOLYSIS . . . . .	578
CYTOTOXINS . . . . .	579
THE BORDET-GENGOU PHENOMENON—FIXATION OF COMPLEMENT	
The Wassermann Reaction, 581.	
THE NEISSER-WECHSBERG PHENOMENON OR DEVIATION OF THE COMPLEMENT . . . . .	583
PRECIPITINS	
General Considerations, 585; Tests for Blood, 587.	
AGGLUTININS . . . . .	589
ANAPHYLAXIS	
General Considerations, 593; Examples of Anaphylaxis, 594; Experimental Anaphylaxis, 594; Specificity, 596; Sensitization by Feeding, 598; Maternal Transmission, 598; Serum Anaphylaxis in Man, 598; Hypersusceptibility and Immunity Produced by Bacterial Proteins, 601; Relation of Anaphylaxis to Protein Metabolism, 602; Relation of Anaphylaxis to Endotoxins, 602; Relation of Anaphylaxis to Tuberculosis, 602; Relation of Anaphylaxis to Vaccination, 603; Relation of Anaphylaxis to Food "Idiosyncrasies," 604; Eczema, 604; Relation of Anaphylaxis to Hay Fever, 605; Relation of Anaphylaxis to Drugs. Anaphylactoid Reactions, 605; Other Practical Relations of Anaphylaxis, 605.	
II. HEREDITY AND EUGENICS . . . . .	607
GENERAL CONSIDERATIONS . . . . .	607
Defectives, 608; Recognition, 608; Mongolianism, 608; Feeble-minded—Idiots, Imbeciles and Morons, 609; Prevention of Propa-	

CHAPTER	PAGE
gation of Defectives, 611; Statistics of Defectives, 613; Degenerate Families, 615.	
EUGENICS . . . . .	619
PRINCIPLES OF HEREDITY	
Variation, 621; Darwin's Theory—the Survival of the Fittest, 621; Mutation, 622; DeVries—Discontinuous Evolution, 622; Weissmann's Views, 623; Mendel's Law, 624; Atavism and Reversion, 628; Galton's Law of Filial Regression, 629.	
THE CELL IN HEREDITY . . . . .	629
STATISTICAL METHODS . . . . .	631
HEREDITY VERSUS ENVIRONMENT . . . . .	638
IMMUNITY GAINED THROUGH INHERITANCE . . . . .	639
III. THE HEREDITARY TRANSMISSION OF DISEASE . . . . .	640
GENERAL CONSIDERATIONS . . . . .	640
Inbreeding, 642; The Microbic Diseases, 643; Congenital Transmission, 644; Hereditary Transmission of a Tendency to a Disease, 644; Tuberculosis, 645; Syphilis, 645; Cancer, 646; Leprosy, 648; Deaf-Mutism, 648; Albinism, 649; Color-Blindness, or Daltonism, 650; Hemophilia, 651; Gout, 651; Brachydactylism, 652; Polydactylism, 653; Fragilitas Ossium, 653; Myopia, 653; Cataract, 653; Retinitis Pigmentosa, 653; Diabetes Mellitus, 654; Orthostatic Albuminuria, 654; Alcoholism, 654; Migraine, 654; Anaphylaxis or Food Idiosyncrasies, 655; Hay Fever, 655; Epilepsy, 655; Huntington's Chorea, 655; Friedrich's Disease—Hereditary Ataxia, 656; Mental Deficiency, 658; Insanity, 658.	

## SECTION V

## FOOD

I. GENERAL CONSIDERATIONS . . . . .	661
THE USES OF FOOD	
General Considerations, 663; Caloric Value of Food, 664.	
CLASSIFICATION OF FOODS	
Physical Properties, 666; Sources, 666; Chemical Composition, 666; Composition and Function, 667.	
VITAMINS . . . . .	669
THE AMOUNT OF FOOD	
Excessive Amounts, 673; Insufficient Food, 674; Famine and Pestilence, 675; War Edema, 675; Underfeeding and Growth, 676.	
UNBALANCED DIETS . . . . .	676
THE DEFICIENCY DISEASES	
General Considerations, 677; Beriberi, 678; Scurvy, 683; Rickets, 685; Pellagra, 686.	
FOOD POISONING	
General Considerations, 692.	
FOOD INFECTIONS	
Incubation Period, 696; Symptoms, 696; Taste, Odor and Appearance, 698; Kind of Food Responsible, 698; Diagnosis, 698; The Colon-Typhoid Group, 699; The Gaertner Group, 701.	
BOTULISM	
General Considerations, 706; Prevalence, 706; Symptoms, 708; Pathology, 710; The Bacillus, 710; Toxin, 712; Antitoxin, 715; Prevention, 716.	

## DECOMPOSED FOODS

General Considerations, 717; Fermentation and Putrefaction, 718; Putrefactive Changes in Proteins, 719; "Ptomain" Poisoning, 721.

ADULTERATION OF FOOD . . . . . 725

## PRESERVATION OF FOODS

General Considerations, 728; Cold, 730; Drying, 733; Salting and Pickling, 735; Jellies and Preserves, 736; Smoking, 737; Canning, 737; Chemical Preservatives, 741.

## THE PREPARATION OF FOOD

Cooking, 749; Methods of Cooking, 751.

## II. ANIMAL FOODS: MILK . . . . . 753

### MILK

General Considerations, 753; Composition, 754; Ferments or "Life" in Milk, 760; Thermal Death Point of Milk Enzymes, 761; "Leukocytes" in Milk, 762; The Excretion of Drugs in Milk, 763; The Differences between Cow's Milk and Woman's Milk, 763; Milk Standards, 764; Grades of Milk, 765; Certified Milk, 767; "Standardized" or Adjusted Milk, 768; Reconstructed Milk, 768; The Decomposition of Milk, 768; Sour Milk and Intestinal Flora, 769; Putrid Milk, 770; Slimy or Ropy Milk, 771; Alcoholic Fermentation of Milk, 771; Bitter Milk, 771; Colored Milk, 772; Adulterations of Milk, 772; Dirty Milk—The Dirt Test, 772; Clarification, 773; Bacteria in Milk, 774; The Germicidal Property of Milk, 776; Diseases Spread by Milk, 777; The Character of Milk-Borne Epidemics, 783; Dried Milk, 784; Fresh Milk Products, 785; Butter, 785; Inspection, 788; Pasteurization, 788; The Effect of Heat upon Milk, 792; The Essential Requirements for a Safe and Satisfactory Milk Supply, 793.

### THE BACTERIOLOGICAL EXAMINATION OF MILK

Number of Bacteria, 794; Kinds of Bacteria, 796.

### THE MICROSCOPIC EXAMINATION OF MILK

The Stewart-Slack Method, 797; The Doane-Buckley Method, 798; The Prescott-Breed Method, 798.

### CHEMICAL ANALYSIS OF MILK

Total Solids, 798; Determination of Total Solids, 799; Determination of Fats, 800; Determination of Milk Sugar, 802; Determination of Proteins, 804; Water, 805; Reaction, 806; Specific Gravity, 807; Field Tests, 808; Heated Milk, 808; Tests for Enzymes, and Their Significance, 808; Tests for the Adulteration of Milk, 810.

## III. ANIMAL FOODS: MEAT, FISH, EGGS, ETC. . . . . 814

### MEAT

Structure and Composition, 814; Nutritive Value, 815; Sources, 816; Recognition of Spoiled Meat, 817; Prevention, 818; Meat Preservatives, 818.

### MEAT INSPECTION

General Considerations, 818; The Abattoir, 820; Qualifications of a Meat Inspector, 822; The Freibank or Three-Class Meat System, 822; Emergency Slaughter, 823; Methods of Slaughter, 824; The United States Meat Inspection Law, 825; Ante-Mortem Inspection, 825; Post-Mortem Inspection, 826.

### ANIMAL PARASITES

Trichinosis, 830; The Pork or Measly Tapeworm, 834; Taenia Saginata, 835; Echinococcus Disease, 836.

## FISH

Physiological Fish Poisoning, 837; Bacterial Poisons, 838; The Fish Tapeworm, 839.

## SHELLFISH

General Considerations, 840; Oysters, 842; Mussel Poisoning, 843.

## BOB-VEAL . . . . . 846

## EGGS

Nutritive Value, 847; Classification, 848; Bacteria in Eggs, 849; Eggs and Disease, 849.

## PLANT FOODS

Tubers, 851; Roots, 851; Fruits, 851; Carbohydrate Food Preparations, 851; How Plants May Injure Health, 851; The Nutritive Value of Plants, 850; Poisoning from Plant Foods, 856.

## SECTION VI

## AIR

## I. COMPOSITION OF THE AIR : . . . . 865

## GENERAL CONSIDERATIONS . . . . . 865

Oxygen, 867; Nitrogen, 869; Argon, 869; Ozone, 869; Hydrogen Peroxid, 871; Ammonia, 872; Mineral Acids, 872; Carbon Dioxid, 872.

## II. PRESSURE, TEMPERATURE, AND HUMIDITY . . . . . 887

## PRESSURE

Normal Atmospheric Pressure, 887; Diminished Atmospheric Pressure, 887; Increased Atmospheric Pressure, 890.

## MOVEMENTS OF THE ATMOSPHERE . . . . . 891

## TEMPERATURE OF THE AIR

General Considerations, 893; Methods of Recording Temperature, 895.

## HUMIDITY

Aqueous Vapor, 896; Methods of Determining Humidity in the Air, 900; Relation of Humidity and Temperature to Health, 904; The Kata-Thermometer, 907; Effects of Warm Moist Air, 910; Effects of Cold Damp Air, 911; Effects of Warm Dry Air, 912.

## III. MISCELLANEOUS . . . . . 914

## ODORS . . . . . 914

## LIGHT—OCULAR HYGIENE . . . . . 916

## ELECTRICITY . . . . . 925

## RADIO-ACTIVITY . . . . . 925

## SMOKE . . . . . 926

## FOG . . . . . 929

## DUST . . . . . 929

## IV. BACTERIA AND POISONOUS GASES IN THE AIR . . . . . 936

## BACTERIA IN THE AIR

General Considerations, 936; Method for Determining Bacteria in the Air, 938; Air and Infection, 939.

## POISONOUS GASES IN THE AIR

Carbon Monoxid, 941; Illuminating Gas, 944; Other Gases in the Air, 946.

## SEWER GAS

General Considerations, 949; Bacteria in Sewer Air, 950; Accidents in Sewers, 951; Illustrative Cases of Death by Sewer Gas, 952; Prevention of Accidents in Sewers, 954; Ventilation of Sewers, 954.

## V. FRESH AND VITIATED AIR . . . . . 955

## THE BENEFITS OF FRESH AIR . . . . . 955

## THE EFFECTS OF VITIATED AIR

General Considerations, 955; The Effects of Increased Carbon Dioxid and Diminished Oxygen, 957; Poisons in the Expired Breath, 958; Physical Changes in the Air, 960; Reinspiration of Expired Air, 963.

## SUMMARY . . . . . 964

## VI. VENTILATION AND HEATING . . . . . 966

## VENTILATION

General Considerations, 966; Air Washing, 968; Recirculation, 968; Vitiating by Respiration, 969; Vital Capacity of the Lungs, 969; Dead-space Air, 970; Factor of Safety, 971; The Amount of Air Required, 971; Standards of Purity—Efficiency of Ventilation, 973; The Size and Shape of the Room, 975; Inlets and Outlets, 977; External Ventilation, 979; Natural Ventilation, 979; Mechanical Ventilation, 984.

## HEATING

General Considerations, 984; Open Fires, 986; Franklin Stoves, 986; Open Gas and Oil Heaters, 986; Hot-air Furnaces, 986; Hot-water and Steam Pipes, 987; Electric Heating, 988; The Cooling of Rooms, 988.

## SECTION VII

## SOIL

## I. GENERAL CONSIDERATIONS . . . . . 991

Classification of Soils, 992; Surface Configuration, 993; Composition of the Soil, 993; Physical Properties, 994; Soil Air, 996; Soil Water, 996; The Nitrogen Cycle, 998; The Carbon Cycle, 1002.

## II. SOIL AND ITS RELATION TO DISEASE . . . . . 1003

Bacteria in Soil, 1003; Pollution of the Soil, 1004; Dirt, 1005; Cleanliness, 1006; Influence of Soil upon Health, 1007; Diseases Associated with Soil, 1007.

## SECTION VIII

## WATER

## I. GENERAL CONSIDERATIONS . . . . . 1015

Composition, 1015; Classification, 1016; Properties, 1017; Uses in the Body, 1017; Amount Used and Wasted, 1018; Dual Water Supply, 1021.

## SOURCES OF WATER

Rain Water, 1022; Surface Waters, 1026; Ground Water, 1032.

## SOURCES AND NATURE OF WATER POLLUTION AND INFECTION

General Considerations, 1043; Simple Tests to Determine Sources of Pollution, 1043; Interstate Pollution of Streams, 1044; Pollution of International Boundary Waters, 1045; The Care of Catchment Areas, 1046.

## II. SANITARY ANALYSIS OF WATER . . . . . 1048

## STANDARD METHODS . . . . . 1048

## ODORS AND TASTE

General Considerations, 1050; Method of Determining Odor, 1051; Prevention and Removal of Tastes and Odors, 1054.

## COLOR

General Considerations, 1055; Method for Estimating Color, 1056; Platinum-Cobalt Standard, 1056.

## TURBIDITY

General Considerations, 1057; Methods for Estimating Turbidity, 1058.

## REACTION . . . . . 1059

## TOTAL SOLIDS . . . . . 1060

## HARDNESS

General Considerations, 1061; Methods, 1063.

## ORGANIC MATTER

Free Ammonia, 1066; Albuminoid Ammonia, 1069; Nitrites, 1071; Nitrates, 1072.

## CHLORIDS . . . . . 1074

## CHLORIN . . . . . 1075

## OXYGEN

Oxygen Consumed, 1077; Dissolved Oxygen, 1079.

## IRON

General Considerations, 1080; Iron Pipes, 1081.

## LEAD

Tests, 1082.

## III. MICROSCOPICAL EXAMINATION OF WATER . . . . . 1084

The Sedgwick-Rafter Method, 1084; Significance of the Examination, 1086.

## BACTERIOLOGICAL EXAMINATION

The Number of Bacteria in Water, 1087; Method for Determining the Number of Bacteria in Water, 1089; Kinds of Bacteria in Water, 1090.

## IV. INTERPRETATION OF SANITARY WATER ANALYSIS . . . . . 1096

## GENERAL CONSIDERATIONS . . . . . 1096

Allowable Limits, 1097; Illustrative Analyses Interpreted, 1099.

## V. THE PURIFICATION OF WATER . . . . . 1108

## NATURE'S METHODS OF PURIFYING WATER

General Considerations, 1108; Evaporation and Condensation, 1109; Self-purification of Streams, 1109; Storage in Lakes and Ponds, 1111.

CHAPTER	PAGE
DISTILLED WATER . . . . .	1112
BOILED WATER . . . . .	1112
FILTERS	
Slow Sand Filters, 1113; Mechanical Filters, 1122; Household Filters, 1127; Scrubbing or Roughing Filters, 1128; Screening, 1128.	
STORAGE . . . . .	1128
SEDIMENTATION . . . . .	1129
CHEMICAL METHODS OF PURIFYING WATER	
Ozone, 1129; Chlorinated Lime—Bleaching Powder or "Chlorid of Lime," 1132; Chlorin, 1139; Permanganate of Potash, 1140; Alum or Sulphate of Aluminium, 1141; Sulphate of Iron and Lime, 1142; Metallic Iron: The Anderson Process, 1143; Cop- per Sulphate, 1143.	
ULTRAVIOLET RAYS . . . . .	1144
VI. WATER AND ITS RELATION TO DISEASE . . . . .	1147
GENERAL CONSIDERATIONS . . . . .	1147
THE MILLS-REINCKE PHENOMENON . . . . .	1148
NON-SPECIFIC DISEASES DUE TO WATER	
General Considerations, 1149; Goiter, 1150; Lead Poisoning, 1155.	
SPECIFIC DISEASES DUE TO WATER	
General Considerations, 1159; Cholera, 1161; Typhoid Fever, 1167; Dysentery, 1179; Diarrhea, 1180; Animal Parasites, 1181.	
SANITATION OF SWIMMING POOLS . . . . .	1182
DRINKING FOUNTAIN . . . . .	1184
ICE	
General Considerations, 1184; Natural Ice, 1186; Manufactured Ice, 1187; Ice and Disease, 1188.	

## SECTION IX

## SEWAGE DISPOSAL

BY GEORGE C. WHIPPLE

GENERAL CONSIDERATIONS . . . . .	1191
Importance of Speedy Removal of Fecal Matter, 1191; Dry Earth System, 1192; Water Carriage System, 1192; Separate and Combined Systems, 1193; Quantity of Sewage, 1194; Com- position of Sewage, 1194; Ventilation and Flushing of Sewers, 1196.	
STREAM POLLUTION	
Sewage Disposal by Dilution, 1196; Hygienic Aspects of Stream Pollution, 1198; Protection against Pollution, 1199; Funda- mental Principles of Sewage Treatment, 1200; Preparatory Processes, 1200; Purification Processes, 1204; Finishing Pro- cesses, 1209; Choice of Methods, 1209; Relative Bacterial Effi- ciency of Different Processes, 1210; Management of Sewage Treatment Works, 1211; Treatment Plants as Nuisances, 1211; Nuisances Caused by Trade Wastes, 1212.	
COÖPERATIVE SANITATION . . . . .	1212
THE RURAL PROBLEM OF SEWAGE DISPOSAL . . . . .	1213

## SECTION X

## REFUSE DISPOSAL

BY GEORGE C. WHIPPLE

	PAGE
GENERAL CONSIDERATIONS . . . . .	1219
Incineration Plants, 1221; Reduction Plants, 1223; Feeding Garbage to Hogs, 1224; Collection of Garbage, 1224.	

## SECTION XI

## VITAL STATISTICS

BY JOHN W. TRASK

GENERAL CONSIDERATIONS . . . . .	1225
VITAL STATISTICS	
Definition, 1227; Development, 1227; Based upon Population, 1228.	
POPULATION STATISTICS	
Source of Data, 1228; Nature of Census Information, 1229; Sources of Error in Census Enumerations, 1229; Fluctuation in Population, 1230; Estimates of Population, 1230.	
MARRIAGE STATISTICS	
Marriage Rates, 1234; Factors Influencing Marriage Rates, 1234; Uses of Marriage Registration, 1234.	
BIRTH STATISTICS	
Registration in the United States, 1235; Birth Rates, 1238; Sources of Error in Birth Statistics, 1239; Uses of Birth Registration and Statistics, 1240; Factors Influencing Birth Rates, 1241.	
MORBIDITY STATISTICS	
General Considerations, 1242; Morbidity Statistics in the United States, 1243; The Model Law for Morbidity Reports, 1245; Results of Notification in Certain States and Cities, 1246; Source of Statistical Data, 1247; Nature of Information Secured by Morbidity Notification, 1251; Standard Notification Blank, 1251; Sources of Error in Morbidity Statistics, 1252; Uses of Morbidity Reports and Statistics, 1253; Morbidity Rates, 1254; Hospital Statistics and Sickness Insurance Records, 1255; Factors Influencing Morbidity Rates, 1255; Notification of Occupational Diseases, 1255; Morbidity Statistics of Military Populations, 1257.	
MORTALITY STATISTICS	
General Considerations, 1259; Registration of Deaths in the United States, 1260; United States Registration Area for Deaths, 1260; Source of Data, 1261; The Standard Death Certificate, 1262; Sources of Error, 1262; Uses of Death Registration, 1266; Death Rates, 1267; Factors Affecting Death Rates, 1270; International List of Causes of Death, 1272.	
INFANT MORTALITY . . . . .	1275
LIFE TABLES . . . . .	1276

## SECTION XII

INDUSTRIAL HYGIENE AND DISEASES OF  
OCCUPATION

GENERAL CONSIDERATIONS . . . . .	1279
SOME FUNDAMENTAL CONSIDERATIONS IN PREVENTION	
General Considerations, 1283; Hours of Work, 1284; Fatigue, 1284; Minors, 1286; Women, 1287; Factory Inspection, 1289; Preventable Accidents, 1290; Sedentary Occupations, 1291.	

## DISEASES OF OCCUPATION

Classification of the Occupational Diseases, 1292; Lead, 1293; Phosphorus, 1303; Arsenic, 1305; Mercury, 1307; Carbon Monoxid, 1308; Hydrogen Sulphid, 1309; Other Industrial Poisons, 1310; Dusty Trades, 1313; The Textile Industries, 1316; Wood Dust, 1319; Mining, 1319; Effects of Heat, 1321; Communicable Infections, 1322; Caisson Disease, 1324.

## SECTION XIII

### SCHOOL SANITATION AND PERSONAL HYGIENE

#### GENERAL CONSIDERATIONS . . . . . 1325

Health Education, 1328; School Building, 1328; The School-room, 1329; The School Furniture, 1330; Posture, 1334; Recess, 1334; Lighting, 1335; Ventilation and Heating, 1336; Open Air Schools, 1337; Water-closets and Urinals, 1337; Cleanliness, 1338; Medical Inspection, 1338; The Communicable Diseases of Childhood, 1341; Closing Schools on Account of Epidemics, 1342; The Eyes, 1342; The Ears, 1343; Oral Prophylaxis, 1343; Nose and Throat, 1346; Diseases of the Skin, 1347; Nervous Diseases and Mental Defects, 1348; Chorea, 1348; Vaccination, 1350.

## SECTION XIV

### DISINFECTION

#### I. GENERAL CONSIDERATIONS . . . . . 1351

Disinfection, 1351; Nature's Disinfecting Agencies, 1353; Cleanliness, 1353; Antibiosis and Symbiosis, 1354; When and Where to Disinfect, 1355; Qualifications of the Disinfectors, 1355; Controls, 1356; Disinfection Must Be in Excess of Requirements, 1356; Specificity of Germicides, 1356; Chemotherapy, 1357; The Ideal Disinfectant, 1357; Concurrent Disinfection, 1357; Terminal Disinfection, 1357; Penetration, 1358; Organic Matter, 1359; Time, 1359; Speed of Disinfection and Stability of Disinfectants, 1360; Temperature, 1360; Emulsions and Solutions, 1361; Dilution, 1362; Reaction, 1362; The Mechanism of Bactericidal Action, 1362; The Choice of Germicide, 1364.

#### THE STANDARDIZATION OF DISINFECTANTS

General Considerations, 1364; Methods, 1365; Carbolic Coefficient, 1366.

#### II. PHYSICAL AGENTS OF DISINFECTION . . . . . 1375

Sunlight, 1375; Ultraviolet Rays, 1375; Electricity, 1377; Pressure, 1377; Burning, 1377; Dry Heat, 1378; Boiling, 1378; Steam, 1379.

#### III. CHEMICAL AGENTS OF DISINFECTION . . . . . 1390

##### GASEOUS DISINFECTANTS—FUMIGATION

Preparation of the Room, 1390; Formaldehyd Gas, 1391; Sulphur Dioxid, 1396; Hydrocyanic Acid Gas, 1402; Chlorin, 1403; Oxygen, 1404; Ozone, 1404.

##### LIQUID DISINFECTANTS

General Considerations, 1404; Methods of Using Chemical Solutions, 1405; Metallic Salts, 1406; Bichlorid of Mercury, 1406; Silver Salts, 1407; Zinc Salts, 1408; Ferrous Sulphate, 1408; Sulphate of Copper, 1408; Coal Tar Creosote, 1408; Carbolic Acid, 1409; Phenol, 1410; The Cresols, 1411; Liquor Cresolis Compositus, 1412; Lysol, 1412; Creolin, 1412; Aseptol, 1412; Asaprol, 1413; Sanatol, 1413; Solveol and Solutol, 1413; Naph-

## CHAPTER

PAGE

thols, 1413; Ambrine, 1413; Naphthalene, 1413; Formalin, 1414; Potassium Permanganate, 1415; Hydrogen Peroxid and Other Peroxids, 1415; Lime, 1416; Bromin and Iodin, 1417; Anti-formin, 1421; Dyestuffs, 1422; Acids, 1422; Alcohol, 1423; Soaps, 1424.

## CONVENIENT FORMULÆ FOR DISINFECTING SOLUTIONS

Bichlorid of Mercury—Corrosive Sublimate, 1425; Formalin, 1425; Milk of Lime, 1426; Carbolic Acid, 1426; Chlorinated Lime, 1426.

- IV. METHODS OF DISINFECTION . . . . . 1439  
 Air, 1427; Stables, 1428; Railroad Cars, 1430; Feces, 1432; Sputum, 1434; Bed and Body Linen, 1435; Books, 1435; Cadavers, 1436; Thermometers, 1437; Wells and Cisterns, 1437.

## SECTION XV

### MILITARY HYGIENE

## GENERAL CONSIDERATIONS

Comparative Loss in Campaign from Sickness and Wounds, 1441.

## RECRUITS AND RECRUITING

General Considerations, 1442; The Physical Examination, 1444; Age, 1444; Character and Mental Condition, 1445; Height, Weight and Chest Measurements, 1446; Vision, 1447; Teeth, 1448; Vaccination, 1448; General, 1448; Training, 1449.

## DUTIES OF THE MEDICAL OFFICER . . . . . 1450

## EQUIPMENT

General Considerations, 1451; The First-aid Packet, 1453; Clothing, 1454.

## DISEASES OF THE SOLDIER

General Considerations, 1458; War Gases, 1459.

## SANITATION IN CAMP AND ON THE MARCH

Personal Hygiene of the Soldier, 1459; The March, 1459; Forced Marches, 1461; Discipline and Sanitation, 1462; Sanitary Police, 1463; Transportation, 1464.

## CAMP SITES

General Considerations, 1465; Topography, 1465; Tentage, 1467; Care of Tents, 1468.

## SANITATION OF BARRACKS AND CAMPS

General Considerations, 1469; Water, 1470; Disposal of Excreta, 1473; Disposal of Garbage, 1475.

## SANITATION OF TRENCHES . . . . . 1478

## HYGIENE IN THE TROPICS . . . . . 1479

## COLD CLIMATES . . . . . 1481

## SECTION XVI

### A LABORATORY COURSE IN PREVENTIVE MEDICINE AND HYGIENE

## SCHEDULE . . . . . 1483

Vaccination, 1484; Standardization of Disinfectants, 1485; Water, 1486; Milk, 1489; Bacterial Vaccine, 1492; Vital Statistics, 1493; Diphtheria Diagnosis, 1496; Classification of Pneumococci, 1498; Meningococcus Isolation and Carrier Detection, 1499; Sanitary Survey of a City or Town, 1501.

## INDEX . . . . . 1505

# LIST OF ILLUSTRATIONS

FIGURE	PAGE
1. Vaccination scars . . . . .	10
2. The course of the eruption . . . . .	13
3. Vaccinia: course of the eruption . . . . .	14
4. Vaccinia: course of the eruption ( <i>continued</i> ) . . . . .	15
5. Course of vaccination and revaccination . . . . .	19
6. Smallpox mortality per 100,000 population in Breslau . . . . .	32
7. Smallpox mortality per 100,000 population in Vienna . . . . .	33
8. Smallpox mortality per 100,000 population in Prussia . . . . .	36
9. Smallpox mortality per 100,000 population in Austria . . . . .	37
10. Chart showing relation of enforcement of muzzling law to prevalence of rabies in Great Britain . . . . .	43
11. Influence of public water supplies on the typhoid fever death rate . . . . .	119
12. Immediate and striking effect of purifying a badly infected water supply upon the typhoid situation . . . . .	121
13. Abrupt reduction in death rates from typhoid fever incident to water purification in four American cities . . . . .	122
14. Hookworms, natural size . . . . .	155
15. Hookworm embryo . . . . .	155
16. Chart showing the decline in the death rate from tuberculosis . . . . .	182
17. Curve of the influenza epidemic in the naval training camp at Pelham Park, New York, September and October, 1918 . . . . .	243
18. West swab tube . . . . .	256
19. Diagram illustrating the method of taking material from the nasopharynx by means of a special swab . . . . .	256
20. A South African blood-sucking fly ( <i>Pangonia</i> ), illustrating long proboscis to pierce heavy fur of certain animals . . . . .	261
21. Example of sealing door for purpose of fumigation . . . . .	267
22. <i>Anopheles punctipennis</i> . . . . .	288
23. <i>Stegomyia calopus</i> (female) . . . . .	297
24. Head of <i>Stegomyia calopus</i> (male) . . . . .	298
25. Eggs of <i>Stegomyia calopus</i> . . . . .	299
26. Larva of <i>Stegomyia calopus</i> . Respiratory siphon of culex to the right . . . . .	300
27. Pupa of <i>Stegomyia calopus</i> . . . . .	301
28. House fly showing proboscis in the act of eating sugar . . . . .	307
29. Eggs of house fly as laid in a mass . . . . .	308
30. Eggs of house fly . . . . .	308
31. Larvæ of house fly . . . . .	309

FIGURE	PAGE
32. Puparium of house fly . . . . .	309
33. Stable fly . . . . .	310
34. Head showing proboscis . . . . .	310
35. Wing of stable fly . . . . .	311
36. The "little house fly" . . . . .	312
37. Wing of house fly, showing how it carries dust particles . .	313
38. The Hodge fly trap on a garbage can . . . . .	315
39. Tsetse fly . . . . .	318
40. The Indian rat flea . . . . .	323
41. The common rat flea of Europe and North America . . .	324
42. The human flea . . . . .	324
43. A squirrel flea . . . . .	327
44. A general scheme for testing plague rat infection, city of Manila	352
45. Isolated plague-infested center, Manila, P. I. . . . .	353
46. The Texas fever tick . . . . .	357
47. Rocky Mountain spotted fever tick . . . . .	358
48. Serbian barrel . . . . .	367
49. Delousing plant . . . . .	371
50. The bedbug . . . . .	379
51. Diagrammatic representation of complement fixation . . .	400
52. The cell with its various combining groups or side chains known as receptors . . . . .	549
53. The toxin molecule: showing the haptophore (combining) group, and the toxophore (poison) group . . . . .	549
54. The first stage of antitoxin formation: a toxin molecule an- chored to a receptor . . . . .	549
55. The second stage: continued stimulation causes a reproduction of receptors . . . . .	550
56. Third stage: The receptors beginning to leave the cell . . .	550
57. Fourth stage: the receptors have left the cell and float free in the blood—antitoxin . . . . .	551
58. The neutralization of a toxin by antitoxin; the free receptors in the blood have united with the toxin—antitoxic immunity	551
59. Showing complement and immune body . . . . .	551
60. Showing an immune body having two affinities . . . . .	552
61. Diagram illustrating deviation of complement . . . . .	584
62. History of the family Zero . . . . .	616
63. History (condensed and incomplete) of three markedly able families . . . . .	618
64. Wilson's theory of inheritance modified by Lock . . . . .	623
65. Diagram showing the course of color heredity in the Andalusian fowl, in which one color does not completely dominate another	626
66. Diagram showing the course of color heredity in the guinea-pig in which one color (black) completely dominates another (white) . . . . .	626
67. Model to illustrate the law of probability or chance . . . .	632

FIGURE	PAGE
68. Normal curve . . . . .	633
69. Curve made up of variates . . . . .	636
70. Family history showing deaf-mutism . . . . .	649
71. Family history showing polydactylism . . . . .	652
72. Family history showing Huntington's chorea . . . . .	656
73. Family history showing feeble-mindedness . . . . .	657
74. Sections through seeds of rice, wheat and corn . . . . .	681
75. Curve showing thermal death point of <i>Bacillus botulinus</i> . . . . .	712
76. Curve showing rate of destruction of botulinus toxin . . . . .	714
77. Unsanitary surroundings of a cowbarn . . . . .	765
78. Conditions under which it is difficult to cleanse and disinfect milk bottles and milk pails . . . . .	773
79. A dark, poorly ventilated cow shed, difficult to keep clean . . . . .	775
80. Automatic temperature recorder for pasteurizers . . . . .	790
81. Strauss home pasteurizer . . . . .	792
82. <i>Trichinella spiralis</i> . Entire life cycle in each host . . . . .	831

# PREVENTIVE MEDICINE AND HYGIENE

## SECTION I

### PREVENTION OF THE COMMUNICABLE DISEASES

#### CHAPTER I

#### DISEASES HAVING SPECIFIC OR SPECIAL PROPHYLACTIC MEASURES

#### **SMALLPOX AND VACCINATION**

The prevention of smallpox depends primarily upon vaccination, secondarily upon isolation and disinfection. Vaccination was the first specific prophylactic measure given to man; it produces an active immunity to smallpox. On account of its importance and great practical value this subject will be considered in some detail, for much of the antivaccination sentiment is due to ignorance or misconstruction of the facts.

Smallpox was once the most prevalent and dreaded disease in the world. Before the days of vaccination only five persons out of a hundred escaped it, and about a quarter of those who took it died. Many of those who recovered were mutilated or maimed for life.

**Historical Note.**—The credit of giving vaccination to the world is due to Jenner, who proved through carefully planned experiments that cowpox protects against smallpox. This fact had been familiar to the farmers and folk of England as a vague tradition for a long time. A young girl who sought medical advice of Jenner, when a student at Sudbury, said, "I cannot take smallpox because I have had cowpox"; this remark made a strong impression upon the young medical student.

Benjamin Jesty, a Dorchestershire farmer, in 1774 successfully vaccinated his wife and two sons. Plett, in Holstein, in 1791 also successfully vaccinated three children. It was Jenner, however, who through logical and scientific methods proved that a person who has had the mild disease, cowpox, enjoys protection against the serious and often

fatal disease, smallpox. Waterhouse and others soon repeated and corroborated Jenner's experiments and helped to establish the soundness of his conclusions.

Jenner made his crucial experiments in 1796, when he transferred the vaccine matter from the hand of a dairy maid (Sarah Nelms) to the arm of James Phipps, a boy about 8 years old. Sarah Nelms scratched her hand with a thorn and "was infected with the cowpox from her master's cows, in May, 1796." Jenner transferred the vaccine virus from the eruption upon the hand of Sarah Nelms to the arm of James Phipps on May 14, 1796. A typical take followed. "In order to ascertain whether the boy, after feeling so slight an affection of the system from the cowpox virus, was secure from the contagion of the smallpox, he was inoculated the first of July following with variolous matter, immediately taken from a pustule. Several slight punctures and incisions were made on both arms, and the matter was carefully inserted, but no disease followed. The same appearances were observable on the arm as we commonly see when a patient has had variolous matter applied, after having either the cowpox or the smallpox.<sup>1</sup> Several months afterward he was again inoculated with variolous matter, but no sensible effect was produced on the constitution."

In addition to such direct experimental proof, Jenner inoculated smallpox matter into ten persons who had at some previous time contracted cowpox.

Date of Inoculation with Smallpox	Name	Ascertained to have had Cowpox
1. 1778	Mrs. H. ———	When very young
2. 1791	Mary Barge	31 years previously
3. 1792	Sarah Portlock	27 years previously
4. } 1795	{ Joseph Merret	25 years previously
5. }	{ William Smith	1, 5, 15 years previously
6. }	{ Elizabeth Wynne	10 months previously
7. } 1797	{ Sarah Wynne	9 months previously
8. }	{ William Rodway	38 years previously
9. After 1782	Simon Nichols	Some years previously
10. Not stated	John Phillips	53 years previously

In justification of such human experimentation it should be remembered that at that time the inoculation of smallpox matter into healthy individuals was an acknowledged method of preventing that disease. Jenner himself was inoculated when a boy. The question of "inoculation" (with smallpox) as contrasted with "vaccination" (with cowpox) will be discussed presently.

With such proof as this Jenner put a popular belief upon a scientific basis. He demonstrated that cowpox is a local and mild disease

<sup>1</sup>This keen observation shows that Jenner was familiar with the modified take, recently rediscovered and now known as the immediate reaction.

in man, that it may be readily transferred from man to man, and that it protects against smallpox. The chain of evidence was complete, but he first proved his thesis to his own satisfaction before he gave it to the world. He said himself: "I placed it on a rock where I knew it would be immovable before I invited the public to take a look at it." Jenner presented the results of his observations to the Royal Society, of which he was a Fellow, but the paper was refused. He then published it in 1798 as a book, modestly entitled, "An Inquiry Into the Causes and Effects of the Variolae Vaccinae, a Disease Discovered in Some of the Western Counties of England, Particularly Gloucestershire, and Known by the Name of the Cowpox." Every student of preventive medicine should read this brief "inquiry" in the original. It may be taken as a model of careful observation and logical presentation, showing great self-restraint and moderation of an observant, imaginative, and judicial mind.

Dr. Benjamin Waterhouse, the first professor of Theory and Practice of Physic in the Harvard Medical School, early became convinced of the value of Jenner's demonstration and obtained some vaccine virus on threads from abroad. On July 8, 1800, he vaccinated his son, Daniel Oliver Waterhouse, then five years old. This was the first person vaccinated in America, so far as existing records show. After successful vaccination with cowpox his two sons and other members of his household were inoculated with smallpox at the Smallpox Hospital by Dr. Zabdiel Boylston, with negative results.

In Boston on August 16, 1802, nineteen boys were vaccinated with the cowpox. On November 9th twelve of them were inoculated with smallpox; nothing followed. A control experiment was made by inoculating two unvaccinated boys with the same smallpox virus; both took the disease. The nineteen children of August 16th were again unsuccessfully inoculated with fresh virus from these two boys. This is one of the most crucial experiments in the history of vaccination, and fully justified the conclusion of the Board of Health—"cowpox is a complete security against the smallpox."

Thomas Jefferson helped materially to spread the new doctrine in this country, and, in 1806, in writing to Jenner, said: "Future nations will know by history only that the loathsome smallpox has existed and by you has been extirpated." This prophecy has by no means been fulfilled—though eminently possible.

### VACCINATION

**Vaccination** may be defined as the transference of the virus from the skin eruption of an animal having vaccinia or cowpox into the skin of another animal. Vaccination, then, consists in introducing the active

principle of cowpox into the skin of a susceptible animal. For over one hundred years vaccination (from *vacca*—a cow) was a specific term limited to the introduction of the virus of cowpox into the skin, in order to induce vaccinia and prevent variola. In recent years, however, the term has been used in a generic sense to include the introduction of many different substances in many different ways and for many different purposes. Thus we speak of attenuated or killed bacterial cultures as bacterial vaccines; and the subcutaneous inoculation of organic substances of diverse origin and nature is often spoken of as vaccination. We hear of typhoid vaccines, anthrax vaccines, staphylococcus vaccines, and we read in the literature of animals “vaccinated” with extracts of cancer and other organic substances. For distinction between a vaccine and a virus, see page 534.

### VACCINE VIRUS

**Vaccine virus** is the living specific principle in the matter obtained from the skin eruption of animals having a disease known as “vaccinia” or “cowpox.” Vaccine virus is obtained from calves, but may also be obtained from older cattle, from man, rabbits, buffalo, camels, and other mammals.

**Cowpox**, or vaccinia, is an acute specific disease to which many animals are susceptible, namely, man, cattle, camels, rabbits, monkeys, guinea-pigs, rats, etc. The disease runs practically the same clinical course in all susceptible species. The eruption is always local and confined to the site of the vaccinated area; the constitutional symptoms are always benign and usually slight. Vaccinia or cowpox is a benign disease; when uncomplicated, it has never been known to cause death or leave any unpleasant sequelae.

After an incubation period of from three to four days the local eruption begins as a papule which soon develops into a vesicle, and later into an umbilicated pustule. Surrounding the vesicle is a reddened, inflamed, and tender areola. The neighboring lymph glands are swollen and tender, and there may be slight fever lasting several days. The pustule dries, leaving a crust or scab, which comes away, disclosing a typical foveated or pitted scar.

**Human and Bovine Vaccine Virus.**—Vaccine virus is usually obtained from (1) bovine or (2) human sources.

*Human virus* is now seldom used, for the reason that the supply would not be sufficient. Upon the appearance of a smallpox outbreak it is sometimes necessary to have enough virus to vaccinate one hundred thousand or more people. Such large quantities evidently could not be obtained from man at any desired time. Another objection to the use of human virus is the possibility of transmitting syphilis, and perhaps

other diseases peculiar to man. It is not always practical to select donors so as to avoid such transmission.

When human seed is used the virus may be transferred directly from arm to arm; or the virus may be preserved dry in the scab; or the contents of the vesicle may be kept in either a dried or moist state, as described below for bovine virus. Arm-to-arm vaccination is still practiced in several parts of the world, particularly in Mexico, where it is claimed that it has the advantage of producing a better take; that the results are surer in that there are fewer unsuccessful vaccinations; and, finally, it is stated that the human virus affords a better immunity, but as to this there is no proof and some doubt.

*Bovine virus* has been used more or less since the time of Jenner, but especially since 1866 when the Beaugency strain was discovered, and more since 1891 when Copeman showed how to purify it with glycerin. It has the great advantage of being readily obtained in any amount and when desired. It may be purified, and it further totally eliminates the danger of conveying syphilis and other diseases peculiar to man.

**Forms of Vaccine Virus.**—Vaccine virus may be used in one of three forms: (1) fresh, (2) dry, (3) glycerinated.

The *fresh* virus may be taken from the eruption of the calf or man and transferred directly. Thus the Institut Vaccinale at Paris still prefers to use the fresh virus. The vesicle is squeezed at its base between the blades of forceps, and some of the content is transferred from the calf directly to the skin of the arm by means of a thumb lancet or any similar instrument.

The vaccinal matter may be *dried*, and the virus remains potent in this state a very long time, especially if kept cold and protected from light. The virus may be dried upon a splinter of ivory, bone, or other substance. Formerly physicians preserved the dried crust from a typical take. When needed, small portions of this crust were ground, moistened, and inserted into the skin.

*Glycerinated* virus consists of vaccine pulp treated with 50 per cent. glycerin. This purifies it and hence is preferable.

**Vaccine Pulp and Vaccine Lymph.**—A distinction is drawn between the pulp and the lymph. The *pulp* consists of the entire vesicle with its contents, which is scraped from the skin, and is composed of epithelium, leukocytes, bacteria, products of inflammatory reaction, the fluid content of the vesicle, débris, etc. The *lymph* is the serous fluid contained in the vesicle or which often exudes from the broken vesicle. When the eruption is produced on the skin of a calf in a large confluent area, the surface of the eruption is scraped away and the exuding "lymph" is placed upon points by dipping or brushing.

Most of the active principle of vaccine virus is contained in the epithelial cells, and this portion is largely lost when only the lymph is

used. The pulp, which includes the lymph, therefore contains the virus in greater concentration, and is almost exclusively used in this country at the present time.

**Dry Points versus Glycerinated Vaccine Virus.**—The old-fashioned dry points were prepared by applying the vaccine lymph to splinters of ivory. Bone or glass were later substituted for ivory. Bone is undesirable because it is difficult to sterilize and may contain tetanus spores. The only advantage of the dry point is its convenience in vaccinating. One disadvantage is that the virus dried upon such points cannot easily be purified as is the case with glycerinated pulp. Further, the points are used as scarifiers and the method of scarification favors irritation and infection of the wound. Dry points practically always contain more bacteria than the glycerinated virus. For these reasons points are no longer permitted in interstate traffic in accordance with the federal regulations.

The best container for single doses of vaccine virus is a capillary tube. These are easily sterilized, filled and hermetically sealed. They should be wiped with alcohol and broken with sterile gauze, and the contents can then safely be emptied by means of a small rubber bulb. When many vaccinations are to be done, it is preferable to have the virus in bulk.

**The Process of Ripening or Aging.**—When the vaccine virus is fresh it is said to be "green." Glycerin is added to the green pulp, and after it has acted a certain period of time the virus is said to be "aged" or "ripe." The use of glycerin for this purpose was introduced by Moncton Copeman<sup>2</sup> in 1891 for the purpose of preserving<sup>3</sup> and purifying the virus. The glycerin acts as a differential germicide, that is, it is comparatively harmless to the active principle in the vaccine virus, but destroys the frail non-spore-bearing bacteria. In time the virus itself succumbs. Vaccine virus must, therefore, not be used while green nor when too old. Manufacturers date their products as "not reliable after" 2 months in the summer time, and 3 months during the cold season.

Fifty per cent. glycerin of the best quality is used. I have shown that no growth of bacteria, yeasts, or molds takes place in 60 per cent.<sup>4</sup> glycerin. Two to four parts of 50 per cent. glycerin are added to 1 part of the pulp by weight. The mixture is then thoroughly ground with a mortar and pestle by hand, or between glass rollers in a special mill driven by machinery. The pulp should be thoroughly broken up and a uniform suspension obtained. The amount of glycerin added depends upon the consistency and character of the pulp. The only objection

<sup>2</sup> Transactions of the International Congress of Hygiene, 1891.

<sup>3</sup> Glycerin also serves as a preservative for other filterable viruses, as foot-and-mouth disease, infantile paralysis, rabies, etc.

<sup>4</sup> Hyg. Lab. Bull. No. 16, U. S. P. H. & M. H. S., 1903.

to adding more glycerin would be the greater dilution of the virus, and, therefore, a larger proportion of negative takes. A higher percentage than 50 per cent. of glycerin soon renders the virus inert. The time required for the virus to ripen depends upon the temperature. Most of the non-spore-bearing bacteria perish in 30 days at 15° to 20° C. Approximately the same effect may be obtained at 37° C. in a few hours. At low temperatures the glycerin has practically no bactericidal effect. The process must always be controlled bacteriologically.

Vaccine virus should always be kept cold until used. The warmth of the doctor's pocket may be enough to destroy its potency in a few hours. The heat of the railroad car or post office may soon render it impotent. This explains the difficulty sometimes encountered in obtaining potent virus during the summer months.

Substances other than glycerin are used for the purpose of purifying vaccine virus. Carbolic acid (0.5 to 1.0 per cent.), in addition to glycerin, is used with success in Japan, and to a large extent in this country. Potassium cyanid, brilliant green, chloroform, chlorobutanol, etc., have been tried, with less success in practice.

**Bacteria in Vaccine Virus.**—Vaccine virus obtained from the skin always contains bacteria. However, these bacteria are, for the most part, harmless to man. They are commonly those that are found on and in the skin of the calf. The non-spore-bearing varieties are largely eliminated by the process of ripening. There are fewer bacteria in the typical unbroken vesicle than in the pustule or in a broken, crusty, inflamed eruption. Green virus may contain from a few thousand to over a million bacteria per cubic centimeter. The ripened, glycerinated virus contains much fewer, and these mostly harmless saprophytes. The number of such bacteria in the ripened virus may be taken as an indication of the care and cleanliness with which the virus has been prepared. In the United States vaccine virus is required to have fewer than 50 bacteria per dose.

Noguchi<sup>5</sup> by painstaking methods obtained a bacteria-free vaccine virus, which may be propagated in the testicles of bulls or rabbits. Human beings react to the testicular strain in an entirely typical manner, but this method has not been found practical for propagation on a large scale.

**Seed Vaccine.**—The seed virus may be obtained (1) from cowpox, (2) from smallpox, (3) by retrovaccination.

"Spontaneous" or casual cowpox occasionally occurs; that is to say, the disease appears to arise spontaneously because its origin cannot be traced. Casual cowpox comes either from another case of cowpox or from a case of smallpox. Cattle are not subject to smallpox, but, when smallpox virus is introduced into the skin of a calf, it produces cowpox.

<sup>5</sup>*Jour. of Exp. Med.*, June 1, 1915, XXI, 6, p. 339.

When smallpox is thus converted into cowpox, it remains fixed as such, and never reverts to smallpox.<sup>6</sup> Twenty-nine separate records of successful modification of smallpox virus into cowpox are found in the literature; also a number of negative attempts. Some of the strains obtained in this way were used to vaccinate children with typical takes and adequate protection.

*Retrovaccination* consists in carrying the vaccine virus back from child to calf; better still, the virus may be passed from man through rabbit, monkey, or other susceptible animal, and then again to the calf. Changing the species helps to maintain the activity of the vaccine virus for an indefinite time; furthermore, the change leaves behind certain associated bacteria which may gather increased virulence by successive passage from animal to animal of the same species.

**Propagation.**—In the propagation of bovine virus young calves are preferred, because they are more manageable, the skin is more tender, and the eruption is therefore more abundant and typical. With young animals a milk diet may be used, which simplifies the problem of dust contamination from dry feed. If hay or fodder is used, it should first be autoclaved. Either heifers or bull calves are suitable, although the former are preferred.

The animals are held in quarantine for seven days, under observation, to determine the absence of infections such as tuberculosis, glanders, foot-and-mouth disease, tetanus, fever, diarrhea or skin eruptions of any kind.

Before vaccinating the calf it is carefully cleaned, and the site of the inoculation is shaved and prepared surgically,<sup>7</sup> but without the use of strong germicidal solutions, for the reason that they are apt to destroy the action of the vaccine virus. Cleanliness and asepsis are the watchwords. The area selected is usually the abdominal wall between the tip of the sternum and the groin, sometimes including the inner side of the thigh. The usual method is to make long, superficial incisions in the skin about one centimeter apart, and the seed virus is gently rubbed into these incisions. The calves must then be kept rigidly isolated in a special room, moderately lighted, free from dust, and screened to keep out insects. The temperature of the animal is taken several times daily and the eruption at each stage of the disease is closely watched and recorded.

The virus is usually taken from the animal about the fifth day. It is an advantage to take the virus early, in order to avoid contaminating infections which may occur when the vesicles mature. Vaccine virus

<sup>6</sup> It is highly significant that casual cowpox was formerly much more common when smallpox was much more prevalent.

<sup>7</sup> I used 3 scrubbings with soap and 3 floodings with alcohol, at the Antitoxin and Vaccine Laboratory, Mass. State Dept. of Health.

taken after the eighth day is unreliable. Jenner's golden rule was to take the virus before the areola appeared. Virus taken after the eighth day is apt to produce unduly inflamed or abortive vesicles, called spurious takes by the early vaccinators. Only typical and entirely characteristic vesicles should be removed. Before the virus is removed, the animal is chloroformed to avoid pain, and an autopsy is done as soon after the virus is removed as practicable. If the autopsy shows any lesions indicating infections other than vaccinia, the virus is discarded.

It is not wise in propagating vaccine virus to vaccinate too large an area. This favors infections by lowering resistance; furthermore, less typical eruptions are obtained than when the area vaccinated is moderate in extent. A yield of from 30 to 50 grams of pulp from one calf should satisfy the propagator.

Before the virus is taken the animal is placed upon a special table, the site of the vaccination exposed and given a very thorough washing and prolonged scrubbing with soap, and an abundant flushing with sterile water. The pulp is obtained by scraping the vesicles with a sharp spoon curette.

Glycerin (50 per cent.) in the proportion 1 to 4 is added at once to the pulp, and this is ground to a state of fine and uniform subdivision in a Csokar lymph mill, or simply by hand with a mortar and pestle. This glycerinated pulp is then allowed to age, and when purified by the action of the glycerin it is hermetically sealed in capillary tubes, or placed in small vials for the market.

## METHODS OF VACCINATION

Vaccination consists in transferring the virus of cowpox from one animal to the skin of another animal. The operation of vaccination consists of introducing vaccine virus *into* the skin. Under no circumstances must the vaccine virus be placed under the skin or subcutaneously. The operation may be compared to the transfer of a culture in a bacteriologic laboratory. Precisely similar precautions to prevent contamination must be used in both cases. Vaccination must be regarded as a surgical operation. No person unfamiliar with surgical cleanliness should be permitted to perform this "little" operation.

The vaccine virus may be introduced in one of three ways: (1) by puncture, (2) by incision, or (3) by scarification.

Jenner used punctures or short incisions. Later blisters were raised upon the skin and the virus placed upon the abraded surface. The incisions were then increased in number, and finally cross scratchings or scarifications were made.

**Puncture.**—The simplest method is shallow oblique pricking of the skin with a needle moistened with the vaccine virus; this gives little chance of contamination and the eruption is typical. The disadvantage is that the virus now used is diluted with glycerin, and therefore somewhat attenuated, so that a few punctures may not give an adequate take.

**Incision or Scratch.**—The method advised and recommended is that of incision. Incision is the only method of vaccination permitted by the laws of Germany, and recommended by the Local Government Board of England. Incision, if not too deep, consists really of a series of punctures, and serves the same purpose. Incisions may be made with the point of a scalpel. I prefer to use a sterile needle. The incision or scratch should not be deep enough to draw blood, but a few drops do

FIG. 1.—VACCINATION SCARS PRODUCED BY METHOD OF SCARIFICATION.

Note unnecessary central scar.

no harm. It is rather difficult to control the depth of the incision with a scalpel, especially if it is sharp. Scratching with a needle is much more easily controlled. Two incisions should be made about one inch long and about an inch apart. The vaccine virus is first placed upon the skin in two

small droplets about an inch apart. The point of the needle is now moistened in the droplet and as the scratch is made the needle carries the virus along with it into the little wound. With the flat of the needle the virus should be gently rubbed (not ground) into the scratch. It is important not to cause any unnecessary irritation so as to avoid attracting infections.

**Scarification.**—Scarification or cross-scratching should be prohibited by law. It is forbidden in Germany. The objection to scarification is that this method produces a relatively large abraded surface which is soon covered by a dry, hard crust of serum and blood, through which the eruption cannot pierce. The vesicles form a ring around the scarified area, leaving a central irritated wound inviting infection. Most of the cases of tetanus complicating vaccination occur in cases in which scarification was used. In this method favorable anaërobic conditions are produced under the crust or scab which forms over the abraded surface. The scarified area also leaves an unnecessary and unsightly scar (Fig. 1).

**The Point of Election.**—The outer surface of the left arm at about the insertion of the deltoid is the most convenient for the operator and the patient. This is the original site selected by Jenner, and is less liable to severe glandular complications than other points. The skin here is easily made taut during the operation by grasping the under side of the arm. Inspection of the course of the eruption is also facilitated.

Flachs recommends the side of the chest at about the level of the sixth rib, in the axilla. Here the scar is not visible; but this site is more objectionable than that recommended by I. H. Goldberger,<sup>8</sup> who uses the inner and back side of the arm.

The leg is sometimes selected to avoid disfigurement. The vaccination scar should not be regarded as a deformity. To the sanitarian a typical vaccine scar is a sanitary dimple. The leg is more exposed than the arm to traumatism, and, therefore, to complications. Dock refuses to vaccinate on the leg unless the patient will stay in bed until the vesicle heals. With babies in diapers and with young children it is exceedingly difficult to keep these parts clean. If the leg is selected, the vaccination should be done on the calf below the head of the fibula, and not on the outer surface of the thigh.

**Number of Incisions.**—This has an important bearing upon the probability of the take, as well as the protection. It is not wise to depend upon one. There is a definite relation between the number of vesicles and the degree and length of the immunity. See page 17. The German regulations of 1899 require at least four incisions, each one centimeter long and two centimeters apart. The Local Government Board of England directs that four vesicles should be produced, and that the total area of the vesicle formation shall not be less than one-half a square inch. My own practice follows that of Dock, who makes not less than two incisions about an inch long and an inch apart; but in case of exposure to smallpox three or four such incisions are advisable.

**The Operation.**—The skin at the site of the operation must be surgically clean, but need not necessarily be treated with germicides. If such are used, they must be carefully washed away in order not to destroy the activity of the virus. A thorough preliminary scrubbing with soap and water is necessary for a dirty skin. Washing with warm water followed by alcohol is usually enough. The alcohol should be permitted to evaporate before the vaccine is applied and the incision is made. In general, the less the skin is irritated the less the danger of complications. Needles are particularly handy, as they may be flamed just before the operation, and are convenient in saving time when many people are to be vaccinated. The vaccine virus is gently rubbed into the incision, not ground in, and then allowed to dry. No dressing is necessary as long as the vesicle remains unbroken, but several layers of dry sterile

<sup>8</sup> *N. Y. Med. Jour.*, Dec. 25, 1920, 112, No. 6, p. 1035.

gauze held in place by adhesive plaster do no special harm, provided they are removed before pustulation. Pads, plasters, and shields of any sort are unwise, because by retaining heat and moisture they cause softening and breaking down; in other words, they act like a poultice.

The best dressing is the unbroken skin, and then the crust (scab) which naturally forms. This permits frequent inspection and avoids undue heat and softening. If the pustule breaks or the crust comes off, or the take shows indications of secondary infection, frequent dressing with an active germicide is indicated. It is not good surgical technic to bind up any actively suppurating area for more than 24 hours.

Painting the vesicle with tincture of iodine, cauterizing the base with silver nitrate, or the application of carbolic acid, picric acid, and other active germicides does not diminish redness or shorten the course of the vaccinal eruption.

Bathing need not be omitted, nor any of the ordinary occupations, but care should be taken not to soften the crust by water or sweat. Unnecessary use of the arm must be guarded against, as this increases the congestion, inflammation, and the chances of infection.

#### INDICES OF A SUCCESSFUL VACCINATION

The take must be typical and the clinical course characteristic, otherwise we have no assurance that the individual is protected against small-pox. The best indices of a successful take are: (1) the course of the eruption, (2) the general symptoms, and (3) the scar.

The importance of knowing the skin lesions of vaccinia were insisted upon by Jenner. Every vesicle, scab, ulcer, or irritated wound is not vaccinia. No confidence should be placed in doubtful or atypical takes. The characteristic features of vaccination are singularly alike. The clinical course of a primary vaccination is as follows:

**Course of the Eruption.**—The primary wound soon heals. Apparently nothing occurs for 3 to 4 days, which is the period of incubation. Then one or more small papules appear upon the skin where the vaccine virus was introduced. The papule is small, round, flat, bright red, hard, but superficial. About the fifth day the summit of the papule becomes vesicular. The vesicle is at first clear and pearl-like. Umbilication soon develops as the vesicle enlarges. A deep, red, and swollen areola surrounds the vesicle and grows wider as the lesion advances. This gives the picture of the "pearl upon the rose leaf" which constitutes the true Jennerian vesicle. By the seventh day the vesicle is full size, round or oval, flat on top, umbilicated, and contents clear. It is multilocular; if pricked with a pin or accidentally opened only that portion of the lymph contained in the compartment opened will exude. By the eighth day it turns yellowish, the middle is fuller, following which the so-called second umbilication develops. Meanwhile the areola

deepens, widens, and may be swollen. The skin feels hot, is painful, and the axillary glands become enlarged and tender. About the tenth day the areola begins to fade and the swelling subsides. By the eleventh or twelfth day the pustule rapidly dries, leaving a brown, wrinkled scab, which finally drops off about the twentieth day. It should never be removed, as it forms the best dressing.

FOVEATED SCAR

FIG. 2.—THE COURSE OF THE ERUPTION (Diagrammatic).

The scar is at first red, finally turns white, with the pits or foveations so characteristic of true cowpox.

**General Symptoms.**—These vary. Malaise, loss of appetite, sometimes nausea and vomiting, headache, pain in the muscles of the back, and other indications of a mild febrile reaction appear about the seventh day, and soon cease. The temperature may go to  $38^{\circ}$  or  $38.5^{\circ}$  C. as the vesicle ripens. The febrile reaction bears no special relation to the size and number of the vesicles or to the areola. The regional lymph nodes become enlarged and tender about the time the pustule forms. The nitrogen elimination increases about the tenth day for a short time. The blood changes resemble those of smallpox, an early leukopenia and secondary leukocytosis.

Secondary vaccinations often run an accelerated, milder, or modified course with shortened periods of incubation (see revaccination).

**Vaccination certificates** should be based upon observation of the course of the take. Modified reactions in revaccinations are to be interpreted as successful takes, but their nature should be recorded—as immediate, or accelerated reactions, page 18.

#### THE IMMUNITY

The immunity appears about the eighth day of the vaccination. Layet puts the point of safety at the ninth day, Burckhard at the elev-

FIG. 3.—VACCINIA. Course of the Eruption.

enth. These data are based upon the early work with variolation, when persons were inoculated with smallpox at various periods following vaccination. Sacco got only a local eruption by inoculating smallpox on the eighth to the eleventh days, and none after that.

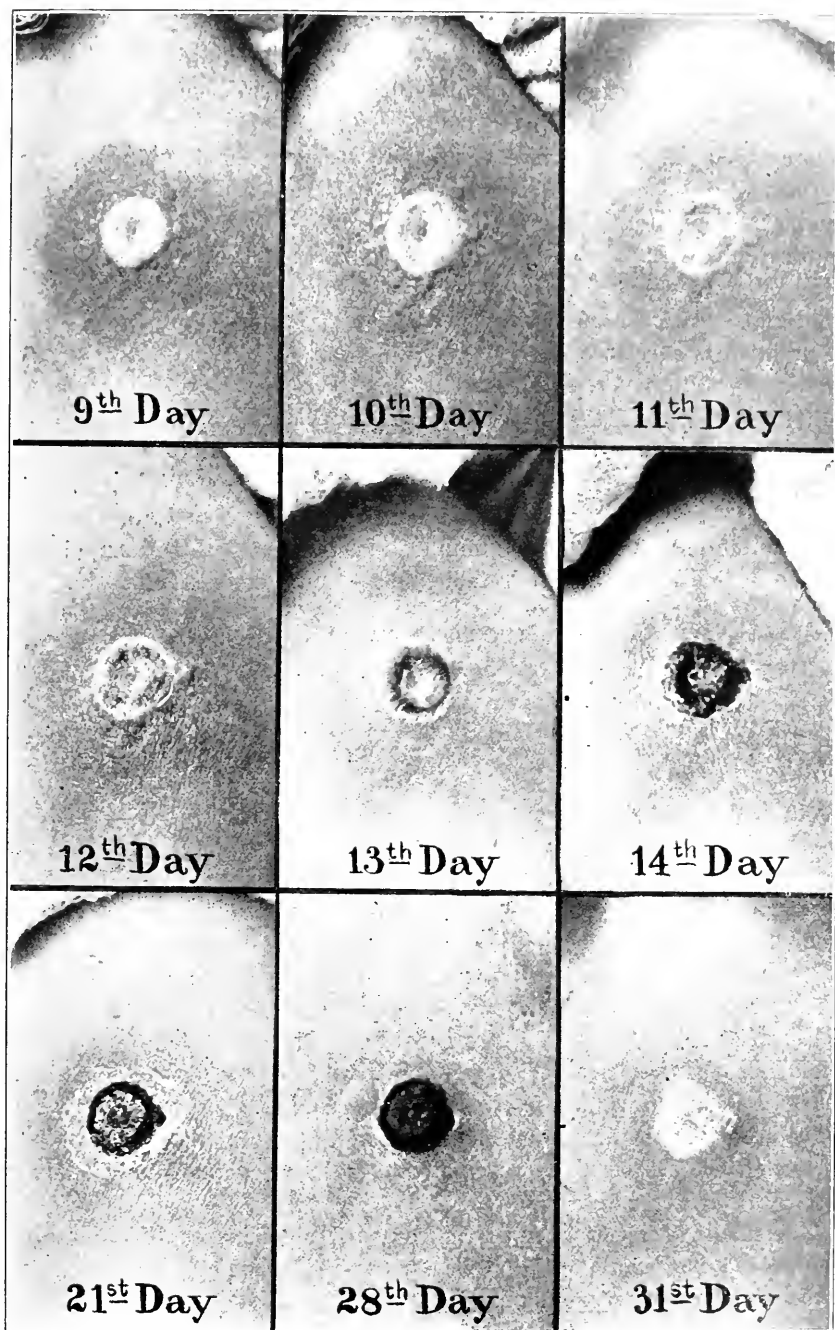

FIG. 4.—VACCINIA. Course of the Eruption.

Vaccinia protects not only against smallpox, but also against vaccinia. Curiously enough, the degree and length of immunity appear to be greater against smallpox than against itself. Persons who have had smallpox may often be vaccinated successfully. It is irrational to attempt to fix a definite time for the duration of the immunity. This varies as in other infectious processes. It is known through experiment and experience that the immunity gradually wears off. The degree of protection is usually absolute for some years, and then gradually fades. Judged by successful revaccinations, it begins to disappear in 2 years and in 10 years is almost completely gone. In this, as in other diseases, immunity is a relative term. Smallpox itself does not always protect against smallpox. Some people have two and even three attacks of smallpox.<sup>9</sup> Such cases, however, are exceptional, and it is also exceptional to have smallpox occur in an individual who has been properly vaccinated.

Careful statistics collected in Japan since 1879 show quite definitely the gradual diminution of the immunity, beginning with the second year after vaccination. Kitasato's table,<sup>10</sup> based on 951 cases, is as follows:

SUCCESSFUL REVACCINATION AFTER

1 year.....	13.6	per cent.
2 years.....	32.9	" "
3 years.....	46.6	" "
4 years.....	57.3	" "
5 years.....	51.1	" "
6 years.....	63.8	" "

Weil, in 1899, reported 72.5 per cent. of successful revaccinations after seven years, 80 per cent. after eight years, 85 per cent. after nine years, and 88.6 per cent. after ten years. German Government reports show 90 to 93 per cent. successful revaccinations after 10 years.

It is commonly asserted that, if a revaccination takes, the subject was therefore susceptible to smallpox. While this is usually true, it does not necessarily follow. It is a still greater fallacy to state that, if a vaccination fails, the subject is therefore immune. This view may result in real harm. Vaccination may fail for many reasons—the operation may not have been properly done, or the virus may have been inert. Sometimes persons are unsuccessfully vaccinated three, four, or more times before a typical take is obtained.<sup>11</sup>

A modified reaction must be regarded as evidence of immunity. Thus, the immediate reaction is a clear indication of immunity, the accelerated reaction of partial immunity.

<sup>9</sup> Jenner mentions "the lady of Mr. Gwinnett, who has had the smallpox five times."—Baron's "Life of Jenner," Vol. II, p. 265.

<sup>10</sup> *Jour. A. M. A.*, March 25, 1911, p. 889.

<sup>11</sup> One of my cases gave a history of having been unsuccessfully vaccinated five times. The sixth attempt produced a typical primary take with 21 vesicles.

There appears to be a definite relation between the immunity conferred and the number of vaccination scars. There is also some evidence that the protection is directly proportional to the area of the local eruption. This question has not been carefully studied since the data contained in the final Report of the Royal Commission on Vaccination, which is summarized in the following table:

MORTALITY OF POSTVACCINAL SMALLPOX IN RELATION TO THE NUMBER OF SCARS

Number of Scars	3,094 cases* (1836-51)	10,661 cases* (1852-67)	6,839 cases†
None	21.7%	39.4%	.....
1	7.6	13.8	6.2%
2	4.3	7.7	5.8
3	1.8	3.0	3.7
4	0.7	0.9	2.2

\* Final Report of the Royal Commission on Vaccination, 1896, paragraph 291. Dr. Thorne, from data collected by Mr. Marson.

† Same Report, paragraph 293. Summary of cases apart from those of Mr. Marson.

One point needs emphasis: The degree and duration of the immunity are directly proportional to the typical nature of the take. No reliance should be placed upon atypical reactions.

The immunity may be renewed; two vaccinations are usually sufficient to protect for life.

The nature of the changes in the body which produce the immunity are not understood. In this sense vaccination is still an empiric procedure. We now know of many analogous instances, however, where an active acquired immunity is induced by means of an attenuated virus. The immunity produced by vaccine virus does not depend upon an anti-toxin. The blood, however, contains specific antibodies, shown by the fact that the activity of vaccine virus is destroyed when mixed with equal parts of blood serum from a calf two weeks after successful vaccination.

#### WHEN TO VACCINATE

The fact that the immunity wears off after a number of years makes it necessary to practice revaccination in order to afford a continuous protection. There is some difference of opinion as to just when it is best to vaccinate the second time. Ten years is too long a period, probably, to depend upon in individual cases. One year—advised by some—is shorter than necessary in most cases. The five-year interval of Japan

is good in many respects, but probably not better than revaccination in the twelfth year obligatory in Germany.

The best time to vaccinate is in the first year, at least before the second summer, and again at from ten to thirteen years. After this it is usually unnecessary to vaccinate again, unless there is particular danger of exposure to smallpox.

All persons exposed directly or indirectly to smallpox should at once be vaccinated and revaccinated until only an immediate reaction is obtained—unless they have had smallpox. There are no contraindications to vaccinating babies immediately after birth, but takes are somewhat less likely than at six months. Vaccination is accompanied by less reaction in young infants than in children, and less in children than in adults.

### REVACCINATION

The clinical picture of secondary vaccinations may be quite different from the typical take following a primary vaccination. These altered reactions were known in the time of Jenner, but were lost sight of until recently rediscovered, and their significance realized from studies in anaphylaxis.

Revaccinations may be divided into three groups: (1) they may run an unaltered course resembling *primary* takes in all respects, showing that immunity to cowpox had disappeared; (2) they may run a somewhat more rapid course in which the period of incubation is shortened and in which the height of the eruption occurs about the sixth day, this is known as the *accelerated* reaction; or (3) they may run a very much shortened, milder, and rapid course. The eruption may be only a small papule which does not develop into a vesicle and slowly disappears; the period of incubation is about 24 hours. This is known as the *immediate* reaction and resembles a cutaneous tuberculin reaction in many respects. Every gradation occurs between an immediate reaction and a primary take. These altered reactions are significant and have been studied especially by von Pirquet and are shown graphically in Fig. 5.

Both the immediate and the accelerated reaction are indications of immunity and therefore should be considered as successful takes. The immediate reaction may be put to practical use in order to distinguish smallpox from chickenpox.<sup>12</sup> Thus, Tièche has shown that smallpox virus introduced into the skin of a person immunized by vaccination will show the typical immediate reaction; whereas the virus of chickenpox is invariably negative. This test can be freed of all possible danger by heating the virus to 60° C. for 30 minutes, which does not seem to affect the reaction.

<sup>12</sup> See also page 395.

## CLAIMS FOR VACCINATION

1. "Duly and efficiently performed it will protect the constitution from subsequent attacks of smallpox as much as that disease itself will."<sup>13</sup>

2. It protects the individual against smallpox for a period which has not been determined mathematically for the individual, but which averages about seven years.

3. The protection may be renewed by a second vaccination.

4. Persons successfully vaccinated on two occasions are usually immune against smallpox for life.

5. Vaccination and revaccination systematically and generally carried out confer complete protection to a community or a nation. In other words, while the individual protection is not always lasting, the communal protection is absolute.

6. A person vaccinated once and at a later time contracting smallpox as a rule has the disease in a less serious form than unvaccinated persons (varioid).<sup>14</sup> The degree of favorable modification of smallpox is in inverse proportion to the period of time elapsing between the vaccination and the attack of smallpox.

7. The beneficial effects of vaccination are most pronounced in those in whom the vaccine affection has run its most typical and perfect course.

## VACCINATION OF EXPOSED PERSONS

The question frequently arises whether persons exposed to smallpox should be vaccinated. The effect of vaccination during the period of incubation of smallpox is very interesting, and may be summed up as follows:

1. Vaccination just before or during the primary fever of smallpox does not influence the disease.

2. If the vaccination is done during the last stage (9th to 14th day) of the period of incubation of smallpox, the two infections run their course side by side without influencing each other.

3. If it is done about the sixth or eighth day of the period of incubation the vaccination takes and may modify the severity of the smallpox.

4. Vaccination done at the beginning of the incubation period, in

<sup>13</sup> "I never expected that it would do more, and it will not, I believe, do less."—Jenner. *Baron's Life*, Vol. II, p. 135.

<sup>14</sup> The term varioid was introduced by Thompson in 1820 to describe the mild and modified form of smallpox occurring after vaccination. The eruption in varioid does not mature and disappears more rapidly than in variola.

Yolfert, Dornbleuth, and Harden showed that one vaccination was not always sufficient protection against smallpox for a lifetime, that revaccination was necessary and that the clinical manifestations of this vaccination are as different from those of the first vaccination as varioid is from variola.

time to have the vaccine eruption reach maturity before the smallpox begins, will prevent or abort the disease.

As we can never be quite sure just what stage in the period of incubation a given case may be in, it is always advisable to vaccinate exposed persons. Furthermore, little harm will be done if it is too late and the vaccine eruption is added to the smallpox. Indeed, Hanna<sup>15</sup> presents claims to the effect that there is evidence of mitigation of the severity of smallpox when vaccination is performed at any time after infection up to the day of onset and even afterward.

### DANGERS AND COMPLICATIONS

The alleged danger from vaccination has been greatly magnified by the antivaccinationists. However, vaccination is not always a harmless procedure; it must be looked upon as the production of an acute infectious disease, and, although the disease is always mild and benign, it must not be treated as trifling. The chief danger lies in the fact that we have produced an open wound, which is subject to the complications of any wound. Even a pin prick or a razor scratch may result in death. While the aggregate number of deaths resulting from the complications of vaccination were considerable, the individual risk is now so small as to be disregarded, especially when proper precautions are taken. Many of the infections after vaccination occur in those in whom the regard for cleanliness is slight, and who neglect the care of the wound. In recent years, owing to the improved quality of the vaccine virus and the introduction of aseptic methods, a bad sore arm is a rare occurrence, and serious complications still rarer. *The danger connected with vaccination is infinitesimal when compared with the benefit conferred.*

The following complications need consideration:

**Auto Vaccination.**—This is usually due to scratching the virus with the finger into the nose, the mouth, the mucous membranes, or any part of the skin. When carried into the eye it may cause blindness. Physicians sometimes vaccinate their lips by blowing into vaccine tubes. In vaccine establishments accidental vaccination of the hand is common.

**Generalized Vaccination.**—This is sometimes reported, but is in my experience a mistaken diagnosis. A generalized eruption of cowpox is exceedingly rare, if it ever occurs. I have seen it once in the calf after intravenous injection of a large amount of the virus, in which case there was a prolonged period of incubation.

The eruption is strictly confined to the point of vaccination. Satellite vesicles sometimes develop in the immediate neighborhood, owing to the spread of the virus into minute nicks in the epithelium.

<sup>15</sup> *Public Health*, July, 1910, XXIII, No. 10, p. 351.

**Wound Infections**, such as ulcers, gangrene, erysipelas, abscesses, lymphangitis, suppuration of the axillary glands, and other septic infections are now exceedingly rare, and demand the usual surgical measures to prevent their occurrence.

**Impetigo contagiosa** occasionally occurs and may be a serious complication of vaccination, especially the rare bullous impetigo or pemphigus which is attributed to special susceptibility or chance infection and not to the vaccine virus.

(Syphilis, tuberculosis, and leprosy were formerly thought of as possibilities when human virus was used, but these are not to be feared with the use of bovine virus.)

**Tetanus.**—*Tetanus* deserves a special word. This serious infection sometimes complicates a vaccination wound just as it may any wound. When we consider the many millions of vaccination wounds, many of which are neglected surgically, it is no surprise to learn that tetanus occasionally occurs as a postvaccinal complication. Acland is acquainted with only one instance in more than five million consecutive vaccinations in England, and even in this one there was no evidence that the tetanus was in the vaccine virus. Over 31,000,000 doses of vaccine were used in the United States from 1904 to 1913 inclusive, yet only 41 authenticated cases of tetanus occurred subsequent to vaccination.<sup>16</sup> A study of these cases makes it clear that the infective principle was not in the vaccine virus, but was received ten days or more after vaccination, owing to the prolonged period of incubation (20.7 days) and the high mortality (75.2 per cent.). The pernicious method of vaccination by scarification was used in almost all cases of tetanus following vaccination. Many of the cases give a history of having the vaccination scab or crust removed in some way, thus permitting infection of the wound with a re-formation of the crust and the establishment of an anaërobic condition. The fact that lack of care is an important factor in postvaccinal tetanus is indicated in the figures from the United States Army and Navy with a record of millions of vaccinations without a single case of tetanus. At the Hygienic Laboratory at Washington vaccine virus representing over two million vaccinations has been examined without finding tetanus. Special tests for tetanus are required by Federal regulations of every lot of vaccine virus before it is placed upon the market. In the Vaccine Laboratory of the State Department of Health of Massachusetts, these tests are conducted in accordance with the Regulations<sup>17</sup> of the U. S. Public Health Service of October 1, 1919, as follows:

Samples of the virus from each calf are tested separately. Only

<sup>16</sup> J. F. Anderson: United States Public Health Report, Reprint 289, July 16, 1915.

<sup>17</sup> Edward Francis, "Laboratory Studies on Tetanus," Hygienic Laboratory Bull., No. 95, August, 1914, U. S. Public Health Service. Also G. W. McCoy and Ida A. Bengston, Hyg. Lab. Bull. No. 115, Oct., 1918.

ground glycerinated pulp kept without preservative for at least 7 days at a temperature of 10° C. or higher is used for the tetanus test. This is to permit the destruction by the glycerin of the most of the frail bacteria. The test virus must not contain phenol or preservative other than glycerin. Two cubic centimeters of the virus is planted in each of four Smith fermentation tubes, each containing at least 25 cubic centimeters of meat infusion broth. These tubes are heated to 100° C. for thirty minutes just before planting in order to expel the oxygen of the air. The tubes are incubated at 37° C. and inspected daily; those showing gas or growth in the closed arm are used to inoculate mice or guinea pigs with one cubic centimeter of the unfiltered broth, not less than twenty-four hours after growth in the closed arm and also nine days after planting. If the animals show symptoms of tetanus, the entire batch of vaccine is discarded. Or:

(a) Plant 0.25 c. c. virus in plain broth fermentation tube. Incubate at 37° C and inject 0.25 c. c. of the growth at the end of 9 days subcutaneously into a mouse.

(b) Plant 0.25 c. c. virus into fermentation tubes of glucose bouillon and incubate immediately. Inject 0.25 c. c. of the growth at the end of 9 days subcutaneously into mice.

(c) Plant 0.25 c. c. vaccine virus into fermentation tubes of glucose bouillon, heat at 60° C. for one hour and then incubate. Inject 0.25 c. c. of the growth into mice at the end of 9 days.

(d) Plant 0.25 c. c. vaccine virus into fermentation tubes of ordinary bouillon, containing a bit of sterile tissue, and inject 0.25 c. c. of the growth at the end of 9 days into mice.

(e) Inject 0.25 of the vaccine virus subcutaneously into guinea-pigs.

If tetanus spores are present in the virus, one of these four methods is almost sure to detect them. The tests are made in duplicate so that a total of 2.5 c. c. of the virus is thus tested.

The occurrence of occasional stray tetanus spores in vaccine virus was demonstrated by Carini.<sup>18</sup> Such vaccine, however, had proved entirely harmless in thousands of cases. Francis also showed that vaccine virus purposely contaminated with tetanus spores will not produce tetanus in monkeys, although it will produce typical "takes."

Glycerin does not destroy the tetanus spore. While the occasional danger cannot be denied, it is plain that postvaccinal tetanus can usually be laid to improper methods of vaccination and to lack of care of the vaccination wound.

To prevent tetanus complications it is important to avoid scarification and irritation, to avoid the use of shields and bandages which favor anaërobic conditions, to require the patient to use strict cleanliness, and to use vaccine virus that has been properly prepared and tested.

<sup>18</sup> *Centralbl. f. Bakt., Orig.* 1904, XXXVII, p. 1147.

**Foot-and-Mouth Disease.**—The infection of foot-and-mouth disease has in one instance been demonstrated as a contamination of vaccine virus.<sup>19</sup> It is, however, impossible to convey foot-and-mouth disease to man through cutaneous inoculation. While no harm has been done to man, the contamination is undesirable, and vaccine virus is tested from time to time to assure its freedom from this infection (page 406).

As an illustration of how seldom complications are caused by vaccination we have the results of Germany, where in thirteen years (1885-1898) 32,166,619 children were vaccinated. Of these 115 died within a few weeks or months after the operation, presumably of injuries incidental thereto. Of these at least 48 probably did not die as a direct result of the vaccination.

The figures of recent years are still better, for it is now exceedingly rare for a death to be recorded as directly due to vaccination.

Ten million vaccinations in the Philippine Islands were done under the direction of American health authorities without the loss of life or limb. Of the millions of vaccinations done in the army and navy during the World War, there is not a single record of serious result. This clearly indicates that with the use of a carefully tested virus and efficient technic, the danger is nil.

#### THE GOVERNMENT CONTROL OF VACCINE VIRUS

By the law of July 1, 1902, the vaccine virus sold in interstate traffic in the United States must come from a licensed manufacturer. These licenses are issued by the Secretary of the Treasury only after a careful inspection of the plant, personnel, and product by a competent government officer. The licenses are good for one year only, and are reissued only after reinspection. The government regulations require each lot of vaccine virus to be examined carefully by modern bacteriological methods to determine the number of bacteria, and special tests must be made to determine the absence of pathogenic microorganisms. These tests include animal inoculations, as well as cultural methods. Special tests for each lot of vaccine must be made to determine the presence or absence of streptococci, tetanus spores, the gas bacillus, and other pathogenic microorganisms, etc. The government does not guarantee the purity and potency of each package of vaccine virus, but through its inspections and frequent examinations of the virus on the market every confidence may now be had in the vaccine virus propagated by licensed manufacturers in this country.

<sup>19</sup> Mohler and Rosenau, U. S. Dept. of Agriculture, B. A. I. Circular 147, June 16, 1909.

## THE UNITY OF COWPOX AND SMALLPOX

The unity or duality of these two diseases has been the subject of much contention. Jenner originally considered cowpox to be a modified smallpox.<sup>20</sup> The successful experiments in Germany, England, and this country, in which smallpox has actually been modified by passing varicellous matter through calves has proved positively that we are dealing with two forms of one disease. Much of the vaccine virus used during the past hundred years was originally obtained from cases of casual cowpox. This virus has been shown by experience and experiments to protect against smallpox, which again makes it highly probable that we are dealing with one disease. See also page 8.

It seems plain that the so-called casual cowpox has its origin from smallpox through accidental inoculation in milking cows by persons having or recovering from smallpox. Once started, the propagation of the modified virus from cow to cow would be comparatively simple.

## COMPULSORY VACCINATION

Vaccination affords a high degree of immunity to the individual, and a well-nigh perfect protection to the community. To remain unvaccinated is selfish in that by so doing a person steals a certain measure of protection from the community on account of the barrier of vaccinated persons around him.

The laws<sup>21</sup> and regulations relating to vaccination in the several states of the United States show marked lack of uniformity. Compulsory general vaccination can be said to exist by law only in Kentucky, Philippine Islands, and Porto Rico.<sup>22</sup> Arizona, Hawaii, Maryland, New Mexico, and North Dakota have laws requiring vaccination of children. Most states or cities have laws requiring vaccination before admission to the public schools.

Decisions in the various courts in the United States have held compulsory vaccination to be legal. A decision of the Supreme Court of the United States (Henning Jacobson vs. The Commonwealth of Massa-

<sup>20</sup> Smallpox is a disease subject to mutations. Since 1898 a mild form of smallpox has existed in this country with a death-rate of about 0.5 per cent. This mild form shows little tendency at present to increase in virulence. Chickenpox itself may belong to the smallpox family. The two diseases are sometimes indistinguishable at the bedside. Jenner always considered cowpox and smallpox as modifications of the same "distemper," and that in using vaccine lymph he was impregnating the constitution with the disease in its mildest form instead of propagating it in its virulent and contagious form. *Alastrim*, *kaffirpox*, *milkpox*, etc., are aberrant forms of smallpox occurring in the tropics, and for public health purposes should be regarded as *variola vera*. These irregular forms of the disease need further study.

<sup>21</sup> Kerr, J. W., "Vaccination, and Analysis of the Laws and Regulations Relating Thereto in Force in the United States," Public Health Bull. 52.

<sup>22</sup> Massachusetts, in 1809, was the first state to enact legislation relative to vaccination.

chusetts, April 1, 1905) upheld in every respect the statute, the validity of which was questioned under the Constitution:

"The liberty secured by the Constitution of the United States . . . does not impart an absolute right in each person to be, at all times, and in all circumstances, wholly freed from restraint. Real liberty for all could not exist under the operation of a principle which recognizes the right of each individual person to use his own, whether in respect to his person or his property, regardless of the injury that may be done to others."

Theoretically it would be ideal if all persons submitted to vaccination and revaccination voluntarily. But experience has shown that this is impractical, and, wherever tried, has failed. The best results have always been obtained where vaccination has been compulsory, and, in my judgment, this is the only present means by which smallpox may be eliminated.

The world may learn a valuable lesson from the splendid results obtained in Germany through compulsory vaccination and revaccination. In England the "conscience clause" allows many persons to remain unvaccinated and thereby seriously diminishes the effects of the vaccination laws of that land. In Minnesota the state health authorities became weary of the clamor against compulsory vaccination and assisted in having the law repealed. They said, in substance, to the people of the state: "Take your choice. Be vaccinated and protect yourself, or run the risk of contracting smallpox; if you get it, it is your own fault."

There is now much smallpox widely distributed in the United States, among a large non-vaccinated portion of the population.

### INOCULATION OR VARIOLA INOCULATA

#### [Variolation]

The practice of *inoculation* or *variolation* must be carefully distinguished from that of vaccination. By inoculation we mean the introduction of *smallpox* virus into the skin of man. The disease thus produced is usually mild, but is nevertheless true smallpox, and just as contagious as smallpox.

This phase of the subject may be made clearer by considering smallpox as existing in three forms: (1) *variola vera* or true smallpox; (2) *variola inoculata* or inoculated smallpox; (3) *vaccinia*, cowpox, or modified smallpox. The differences between these affections are shown in the table on the following page.

Emphasis must be placed on the fact that *variola inoculata*, while usually a mild disease, is just as communicable as true smallpox, and those who contract the disease in this way get true smallpox, sometimes in serious or fatal form. *Inoculation, therefore, protects the individual but endangers the community.*

<b>Variola Vera</b>	<b>Variola Inoculata</b>	<b>Vaccinia or Cowpox</b>
True smallpox.	Inoculated smallpox.	Modified and attenuated smallpox.
Occurs only in man.	Occurs in man and monkeys.	Man, monkeys, cattle, guinea-pigs, rabbits, rats, camels, and many other mammals.
High mortality.	Milder; rarely fatal; about 1 in 500.	Very mild; never fatal.
A general eruption, often confluent or hemorrhagic.	A local and a general eruption, fewer pustules (rarely over 200); seldom confluent or hemorrhagic.	Always local and confined to the site of the vaccination.
Highly contagious.	Equally highly contagious.	Not contagious—contracted only by mechanical transfer of vaccine virus.
Period of incubation 12-14 days.	8 days.	3-4 days.

Inoculation is a very old custom. It was practiced by the Chinese from time immemorial. The method was introduced into western civilization through Lady Mary Wortley Montagu, who learned of the method at Constantinople and had her own boy "engrafted" with successful result. In 1717 Lady Montagu wrote her now famous letter to her friend Sarah Chiswell, and the practice soon became popular in England (1721) and spread to America and the Continent.<sup>23</sup> It was introduced into this country by Dr. Zabdiel Boylston at Boston. But the dangers were early realized and inoculation was soon replaced by vaccination. According to Plehn, inoculation is still practiced in central Africa.

The method of inoculation is precisely similar to that of vaccination. The matter is obtained from the vesicle or pustule of a case of smallpox. This material is then introduced into the skin by means of a puncture, an incision, or through an abraded surface. The Chinese inoculate usually by plugging the nostrils with cotton previously saturated with a mixture of water and pustular-crustaceous matter taken from the eruption of a smallpox patient; less commonly by blowing the crushed fresh crusts into the nostrils through a bamboo pipe.

Following the inoculation of smallpox virus a local eruption appears on the fourth day at the site of the inoculation. This local eruption resembles vaccinia but develops more rapidly. Constitutional symptoms appear on the evening of the seventh or the morning of the eighth day following the inoculation. These symptoms resemble the onset of true smallpox and are rigor, headache, vomiting, and fever. The local erup-

<sup>23</sup> The practice of inoculation had been published in England as early as 1714 by Dr. Timoni of Constantinople; at Venice in 1715 by Pylarini, and in the same year in London by Mr. Kennedy, a surgeon who had been in Turkey. Its adoption and subsequent diffusion, however, were due to Lady Mary Wortley Montagu.

tion subsides on the appearance of the febrile symptoms but at the same time the general eruption breaks out. The crop is usually discrete, moderate in number, but runs the usual course through papule, vesicle and pustule formation.

Inoculation has fallen into disuse only because we have vaccination. There are conceivable emergencies in which the practice would be justified. For example, on board ship or on an island or isolated place, in the absence of vaccine virus. Under such circumstances it would be essential to inoculate everybody at the same time.

The inoculation of smallpox will always remain for the student of hygiene one of the most interesting episodes in the development of preventive medicine. It illustrates in the clearest manner some of the fundamental phenomena of infection, susceptibility, and immunity. It was animal experimentation on a huge scale, the like of which we shall never see repeated on man as the subject. It is now a matter of regret that for the sake of science better advantage was not taken of the data.

### PREVALENCE OF SMALLPOX

It is very difficult for us now to realize that smallpox was once much more common than measles and much more fatal. Many of those who recovered were disfigured for life, left blind, or with some other serious consequence of the disease. For centuries smallpox was one of the greatest scourges. It depopulated cities and exterminated nations. In Europe alone, where its ravages were comparatively slight, it killed hundreds of thousands yearly. In the 18th century, of which we have the best records, almost everybody had it before he grew up. Parents often exposed their children to the disease in order to be through with it, just as they now sometimes do with the minor contagious diseases.

Smallpox was formerly a disease of children. It was called *Kinderblättern*. Since vaccination protects the child, smallpox has now become more prevalent among adults.

The distinguished mathematician, Bernouille, estimated that 15,000,000 people died of smallpox in 25 years in the 18th century. It has been estimated that 60,000,000 people died of smallpox during that century. Haygarth gives an account of a smallpox epidemic in Chester, England, population 14,713. At the termination of the epidemic there were but 1,060 persons, or 7 per cent. of the population, who had never had smallpox. Many similar instances are cited in the literature. The French physician de la Condamine (1754) said that "every tenth death was due to smallpox and that one-fourth of mankind was either killed by it or crippled or disfigured for life." Sarcene (1782) estimated the

number of persons in Italy who suffered from smallpox as 90 per cent. of the population.

Smallpox was introduced into the western hemisphere by the Spaniards about fifteen years after the discovery of America. In Mexico within a short period 3,500,000 persons are said to have died of the disease (Chapman). Catlin (1841) states that of 12,000,000 American Indians 6,000,000 fell victims to smallpox. In Iceland, in 1707, 18,000 perished out of a population of 50,000, that is, smallpox killed 36 per cent. of the total population in one year.

A good example is that of Boston in 1752, population at that time 15,684. Of this number 5,998 had previously had smallpox. During the epidemic 5,545 persons contracted the disease in the usual manner, and 2,124 took it by inoculation. One thousand eight hundred and forty-three persons escaped from the town to avoid infection. There were, therefore, left in the city but 174 persons who had never had smallpox.

Smallpox is still as serious as it was in former times. Thus, in five years, from 1893-1897, 346,520 persons died of smallpox in sixteen countries. Of this number Russia alone lost 275,502. These figures are the more terrible when it is realized that these lives might have been saved by the use of a simple prophylactic measure within reach of all.

### EPIDEMIOLOGY

Few of the acute infectious diseases show such a complete independence of conditions such as race, climate, soil, age, sex, and occupation, sanitary surroundings, etc., as does smallpox. It thrives wherever the contagion is carried, and wherever it finds susceptible people. Probably no one is naturally immune. The susceptibility of an unvaccinated population varies, because a smallpox outbreak leaves so many immune. This is one reason why the disease recurs in waves. The mortality varies greatly in different epidemics. At times it is less than one per cent.; it frequently reaches thirty per cent. and over.

From 1897-1912 the mortality in the United States varied from 0.34 per cent. to 6.2 per cent.; in 1895 it was 20.84 per cent., and following that 0.5 per cent. These differences occurred in the prevaccination era as well as now. There seem to be two distinct strains in the United States, one the classic smallpox of the text books, the other a very mild form.

The epidemiology of smallpox bears no relation to improved sanitation, which has diminished the prevalence of plague, typhoid, cholera, and has practically subdued typhus and relapsing fever. It is evident that general sanitation could not affect contagious diseases like smallpox and measles. Smallpox spares neither the high nor the low, the rich nor the poor, the clean nor the dirty; before the days of vaccination it

counted many kings, queens, and princes among its victims. George Washington contracted smallpox in the West Indies.

### *MODES OF INFECTION*

We are still ignorant of the precise mode by which smallpox is conveyed. The view generally held is that the infection is air-borne and enters the system through the respiratory mucous membranes. It has been surmised that a local lesion may be produced in this favorable soil, the so-called "propustule," from which general infection through the blood takes place. The blood infection is marked by a sharp onset (the initial symptoms), and the skin eruption is embolic in character. The objection to this view is that a careful search at 54 autopsies in Boston by Councilman and his colleagues failed to find such a propustule.

The Chinese inoculate the disease by placing variolous matter in the nostrils, but the disease so produced is said to resemble variola inoculata.

The virus of smallpox is contained in the skin lesions. Of this we have experimental evidence. It is also supposed to be in the expired air. This, however, has never been experimentally proved and is doubtful. The disease is contagious before the eruption appears. It is even believed to be communicable during the period of incubation. Smallpox has always been taken as the type of the contagious diseases; the contagion appears to be the most "volatile" of any of the diseases of man with the possible exception of measles and influenza. This volatility, however, has been over estimated, and, while probably an air-borne infection, the radius of danger is contracted. English observers have long taken the view that smallpox may be blown for great distances, and they attribute the prevalence of smallpox to the windward of hospitals as an indication that the virus may be carried down the wind. My experience with the disease teaches me that the danger from such a source is practically nil. One may safely live next door to a smallpox hospital that is well screened and properly managed. The influence of flies and other insects, or surreptitious visiting, may account for the spread of this disease outside of hospital walls.

In addition to more or less direction contact, smallpox may be spread indirectly in a great variety of ways. The secretions from the mouth and nose doubtless contain the infection, and, while suspicion has not particularly fallen upon the feces and urine, it is probable that all the secretions and excretions from the body may be infective at some time throughout the disease, or during convalescence. Toys, pencils, spoons, cups, towels, handkerchiefs, bedding, and objects of the greatest variety that have in any way come in contact with the patient may carry the infection. Under favorable circumstances the active principle may prob-

ably live for a considerable time upon fomites, although the practical danger from this source is not very great.

Smallpox is not usually considered an insect-borne disease, but it is highly probable that a fly lighting upon a smallpox patient and getting its proboscis, feet, and other portions of its body smeared with the variolous matter, and then flying to a susceptible person, could thus readily transmit the infection. Other insects may by such mechanical transfer play a similar rôle.

### RESISTANCE OF THE VIRUS

It is generally, and doubtless correctly, assumed that the active principle of variola has approximately the same resistance to external conditions as vaccine virus. This assumption is confirmed by experimental evidence, which shows that the virus of smallpox is somewhat more readily destroyed than the virus of cowpox. Scientific data concerning the viability of variolous matter is meager, owing to the fact that this question can only be settled by prolonged and repeated experiments upon monkeys. Brinckerhoff and Tyzzer<sup>24</sup> found that variolous virus is less resistant to desiccation than vaccine virus; that variolous virus does not pass a Berkefeld filter and is attenuated by long exposure to 60 per cent. glycerin.

In general it may be said that variolous virus is killed by exposure to ordinary germicidal substances, both liquid and gaseous, in the strengths and time commonly employed. It succumbs in fact before the average non-spore-bearing bacteria.

There is an exception to this statement in the case of carbolic acid and the coal-tar disinfectants. McClintock and Ferry<sup>25</sup> have shown that such germicides as carbolic acid, cresols, and the like do not destroy the virulence of vaccine virus in 0.5 per cent. solutions in five hours' exposure.<sup>26</sup> Noguchi found that 1 per cent. phenol has no injurious effect upon emulsions of the testicular strain of vaccine virus. The inference is allowable that this class of disinfectants cannot be relied upon to prevent the spread of smallpox.

Glycerinated virus is very susceptible to heat.

### SMALLPOX IN THE VACCINATED AND UNVACCINATED

The experience of over one hundred years offers convincing proof of the pronounced difference in the mortality and morbidity from smallpox in the vaccinated and the unvaccinated.

<sup>26</sup> *Jour. Exp. Med.*, March 1, 1918.

FIG. 6.—SMALLPOX MORTALITY PER 100,000 OF POPULATION IN BRESLAU. No compulsory vaccination before 1874; since then compulsory vaccination and revaccination.

Fig. 7.—SMALLPOX MORTALITY PER 100,000 OF POPULATION IN VIENNA. No compulsory vaccination in Vienna, but since 1891 the administrative government authorities have used their best efforts in furthering vaccination. (Compare with Fig. 6.)

In countries like Germany, Sweden, Ireland, Scotland, the Philippine Islands, Porto Rico, and England, where vaccination is more or less compulsory, there is comparatively little smallpox. In countries like Belgium, Russia, Austria, and Spain, which have no compulsory vaccination laws, smallpox yearly claims many victims. See the following table:

TABLE 1.—DEATHS FROM SMALLPOX IN COUNTRIES WITH COMPULSORY VACCINATION AND THOSE WITHOUT COMPULSORY VACCINATION

Population		Smallpox Deaths				Average of Deaths	Average per Million of Pop.
		1886	1887	1888	1889

\* Compulsory vaccination.

April 8th, 1874, Germany passed a general compulsory vaccination and revaccination law. The law requires the vaccination of all infants before the expiration of the first year of life, and a second vaccination at the age of twelve. Since this law went into effect there have been no epidemics of smallpox in Germany, despite the fact that the disease has been frequently introduced from without. In 1897 there were but 8 deaths from smallpox in the entire German empire—population 54,000,000. Since then long periods have passed without a single death from smallpox. From 1901 to 1910 there were only 380 deaths from smallpox in Germany; during the same period there were 4,286 deaths from smallpox in England and Wales, with only about half the population of Germany; furthermore, many of the deaths in Germany were in foreigners. Thus in 1909, out of 26 deaths from smallpox, 13 were foreigners, 11 of whom were Russians. In 1911, there were 288 cases of smallpox in the German Empire. Of these, 119 were of foreigners. In 1912, there were 340 cases, of which 153 were foreigners. In 1913, there were only 90 cases, of which 39 were in foreigners. During the World War, the large number of Russian prisoners in Germany caused a marked increase of smallpox in the civil population. In the huge German army there were only two deaths from smallpox from 1874 to 1914. One of these was a reservist who had not been successfully vaccinated. Germany has demonstrated how to utilize Jenner's great discovery.

*ISOLATION AND DISINFECTION*

Isolation and disinfection are only secondary measures in preventing smallpox. They cannot be regarded as substitutes for vaccination.

Isolation should be carried out with strictness for the reason that smallpox is one of the most contagious of the communicable infections. While the patient should be isolated, it is not necessary to isolate the hospital by banishing it to an inconvenient or undesirable location. There is, in fact, no good reason why a smallpox hospital should not be one of the units of the general hospital for communicable diseases. In any event, there is no danger from a smallpox hospital situated upon a highroad or near other habitations, provided always proper precautions are taken to prevent the spread of the disease.

The smallpox hospital should not be a pesthouse, but should be as inviting and attractive as economic conditions justify. Smallpox should not be treated in the home. From the standpoint of prophylaxis the hospital is the logical and best place to care for this and other communicable infections. If smallpox is treated in the home, this should only be permitted if skilled nursing and trained attendants can be provided.

The room in which the smallpox patient is isolated should be simply furnished to facilitate cleanliness and to permit purification. It must be well screened and free from insects and vermin of all kinds. The room should be well ventilated. This may be accomplished by an open fireplace, in which case the contagium, if contained in the outgoing air, is burned in exit.

The nurse attending a case of smallpox should also be segregated, and all visiting should be strictly interdicted. A separate kitchen should be provided and care should be taken that the dishes be scalded and remnants of food burned.

Bedding, underwear, towels, and other objects should not leave the sick room unless they are first boiled, steamed, or immersed in a suitable germicidal solution, such as bichlorid of mercury, 1-1,000, or formalin, 10 per cent. Carbolic acid should not be trusted.

For terminal disinfection cleansing of surfaces with a germicidal solution is much surer than gaseous fumigation. Objects particularly contaminated or soon to be used by others should be given a separate and special disinfection. Finally, the room should be thoroughly cleansed, aired, and sunned.

The patient must be regarded as the source and fountainhead of the infection, and measures should be used at the bedside to prevent the surroundings from becoming contaminated. Cloths, cotton, and other dressings that become soiled with the contents of the vesicles and pustules after they break should be burned. The urine and feces may

FIG. 8.—SMALLPOX MORTALITY PER 100,000 OF POPULATION IN PRUSSIA. (Compare with Austria, Fig. 9.)

FIG. 9.—SMALLPOX MORTALITY PER 100,000 OF POPULATION IN AUSTRIA. There was very little difference in the number of deaths from the disease in Prussia and Austria as long as compulsory vaccination had not been introduced; since the enactment of the German Vaccination law in Prussia, however, the mortality there has sunk to a previously unknown figure, whereas it has remained stationary and at the same high rate in Austria for many years. Up to 1889 the mortality from smallpox in the latter country was on an average greater than it was before the epidemic in 1872, and it is only since 1890 that favorable conditions have again prevailed, although the losses from smallpox have remained greater during recent years than in Prussia.

be disinfected with chlorinated lime. The sputum and discharges from abscesses should be collected on cheap cloths and burned. As a rule, smallpox patients are not dismissed from quarantine until desquamation has ceased. This may be favored by the use of warm baths and a generous use of glycerin soap, also by anointing the skin with vaselin or a bland oil. Special attention should be given to the hair, which should be well shampooed; to the interdigital spaces, and the fingernails, as well as to all folds of the skin, before the patient is released.

The management of a smallpox epidemic is discussed on page 495.

## RABIES

**Synonyms.**—*Hydrophobia*; *Wasserscheu*. *Wut*, *Tollwut* (German); *Lyssa* (Greek); *La Rage* (French).

Rabies is an acute, specific, rapidly fatal paralytic infection communicated from a rabid animal to a susceptible animal, through a wound usually produced by biting. Man always contracts the disease from some lower animal, usually the dog. The infective agent must be inoculated into the tissues; the virus is harmless when ingested, provided the mucosa is intact. The gastric juice has a pronounced deleterious effect upon the virus. Rabies may be regarded as a wound infection. The specific principle is contained in the saliva of animals suffering with the disease. The infection, therefore, may be conveyed by licking, etc.,

provided there are fissures or open wounds in the skin. It is also possible to introduce the virus through autopsy accidents and other unusual ways, but commonly it is introduced through wounds produced by the teeth of a rabid animal.

Every mammalian animal is susceptible. Even birds may contract the disease. It is most common in dogs, but it also occurs frequently in wolves, jackals, foxes, and hyenas. Rabies in cats is comparatively rare. Cattle, sheep, and goats are infected relatively in about the same degree. It is less common in horses. Swine contract the disease less frequently than other domestic animals. Skunks may contract the disease and sometimes transmit it to man.

Although all mammals are susceptible to rabies, it is perpetuated in civilized communities almost exclusively by the domestic dog, only to a small extent by wild animals of the dog family, and occasionally by skunks, cats, etc.

Rabies exists practically all over the world. It has never been in Australia, and has not been known in Denmark, Norway and Sweden for more than fifty years. Rabies had been eradicated from England, but was reintroduced during the World War by dogs carried in flying machines. It is most common in France, Belgium, and Russia. In France, rabies of a virulent type with a short incubation period has spread since the first of the World War. In the United States 111 human deaths were reported in 1908. In the same year there were 535 localities in which rabid animals were reported; in 1911 there were 1,381 localities, and 98 deaths in man. In 1890 the United States census reported 143 deaths in 30 states, and in 1900 but 23 deaths. In 1916, 21 deaths were reported from 11 states. In 1919, 45 deaths were reported in the United States.

Rabies is remarkable on account of its high mortality—practically 100 per cent. After symptoms are pronounced recovery rarely, if ever, takes place. Joseph Koch (1910), however, describes an abortive rabies. The disease is peculiar in several other particulars, especially the period of incubation, which is more variable and more prolonged than that of any other acute infection.

Rabies is commonly supposed to prevail only during the hot months, but it is in fact more prevalent in cold weather. Exposure to cold seems to increase its virulence. More dog bites occur from April to September than from October to March in this climate, because dogs run abroad more freely at this season of the year.

**Period of Incubation.**—From the standpoint of prevention it is fortunate that the period of incubation of this disease is prolonged. This period varies from 14 days to a year or more. Such prolonged periods of incubation indicate latency. The average period is as follows: Man, 40 days (apt to be shorter in children); dogs, 21-40 days; horses, 28-56

days; cows, 28-56 days; pigs, 14-21 days; goats and sheep, 21-28 days; birds, 14-40 days.

The period of incubation depends largely upon the site of the wound, the relation to the nerve, the amount and virulence of the virus. It requires about 15 days, counting from the last injection, to induce an active immunity to the disease by means of the Pasteur preventive treatment. There is, therefore, usually sufficient time, if the case is seen early, to prevent the development of symptoms.

It is probable that the prolonged period of incubation is due in part to the fact that it takes time for the virus to travel along the nerves to the central nervous system, and also to the fact that after the virus reaches the central nervous system, it may remain dormant (latent) until favorable conditions permit multiplication and the production of toxic effects.

**Entrance and Exit of the Virus.**—The active principle of rabies occurs principally in the saliva and in the central nervous system. It may be in the saliva at least three days (possibly eight) before the animal shows symptoms (Roux and Nocard). It is, therefore, sufficient to watch a dog that has bitten a person or another animal for ten days. If no symptoms of rabies appear during this time there is no danger of conveying the disease, and the Pasteur prophylactic treatment is unnecessary.

The virus has been found in the adrenals, the tear glands, the pancreas, the vitreous humor, the spermatic fluid, the urine, the lymph, the milk, as well as all parts of the central nervous system and the peripheral nerves. It is also found in the spinal and ventricular fluids. It has not been demonstrated in the liver, spleen, blood, or muscles.

The virus enters the system through the broken skin and follows the nerve trunks from the seat of injury to the spinal cord, thence to the medulla and brain. The route corresponds to that of tetanus toxin. The mode of invasion of the virus may explain why pain, throbbing, tingling, numbness and other nervous disturbances are the first symptoms to occur in parts of the body that have received the virus. It also partly explains the variable period of incubation, which is shorter in wounds of the face than wounds of the extremities. It also explains why the disease is more liable to occur when the wounds are in parts of the body with a rich nerve supply. I have experimental evidence (unpublished) that indicates that the virus readily enters the nerve endings in the skin.

Noguchi<sup>27</sup> announces that he has succeeded in growing the virus, which appears in cultures as granular and pleomorphic chromatoid bodies, some of which are surrounded with membranes. Williams<sup>28</sup> and

<sup>27</sup> Noguchi, *Jour. Exp. Med.*, 1913, XVII, 29.

<sup>28</sup> Williams, Anna Wessel; *Jour. A. M. A.*, 1913, LXI, 17, p. 1509.

Moon<sup>29</sup> believe they have evidence of growth in brain tissue, having produced rabies in animals in the fifth generation or transfer of such "cultures."

**The Relative Danger of Bites.**—Wolf bites are most dangerous on account of the savage character of the wound, and the virulence of the virus. Cat bites come next, and then dog bites. The relative danger of bites of other animals is as follows: foxes, jackals, horses, asses, cattle, sheep, pigs. There is no authentic instance of the transmission of the disease by the bite of man, though this may be possible. The bites of horses and other herbivora are less dangerous because their blunt teeth usually cause contused wounds without breaking the skin.

Bites on exposed surfaces are more dangerous than through the clothing, because the saliva is wiped from the teeth and little or none enters the wound. Long-haired dogs and sheep often escape infection for the same reason. Bites upon the face are most apt to be followed by rabies.

Not every person bitten by a mad animal develops rabies. Leblanc's figures are 16.6 per cent. The statistics are difficult to analyze, and it is almost impossible now to collect sufficient data. According to the most reliable figures, it would seem that rabies develops in not less than one person in ten bitten by mad dogs, and not receiving the Pasteur treatment. Paltauf places the figures at 6 to 9 per cent. From 15 to 20 per cent. is a moderate estimate of the death rate for all persons bitten by rabid animals. See also page 49.

**Viability.**—The virus of rabies in the spinal cord of rabbits dies in about 14 days when dried at 20°-22° C., if protected from putrefaction and light. Spread in thin layers, it dies in 4 or 5 days, and exposed to the sunlight in 40 hours. It is quite resistant to putrefaction. In a decomposed carcass it may be recovered by placing some of the central nervous system in glycerin. The glycerin destroys most of the contaminating bacteria, but preserves the virus. Rabic virus is completely destroyed at 50° C. in one hour, and at 60° C. in 30 minutes. It is not injured by extreme cold.

Harris found the virus to be very resistant to dryness at low temperatures. Rabic virus in central nervous tissue is very resistant to ordinary germicides. Sawtschence<sup>30</sup> found that it requires from five to seven days to destroy the fixed virus in 5 per cent. phenol, and that it is not destroyed by 0.5 per cent. phenol in 20 days. Other filterable viruses, notably variola and vaccinia, also show unusual resistance to phenols and cresols. Semple<sup>31</sup> found that the emulsion of fixed virus which resists the action of 1 per cent. phenol at room temperature for

<sup>29</sup> Moon, *Jour. Infect. Dis.*, 1913, XIII, 232.

<sup>30</sup> Sawtschence, W., *Ann. de l'Inst. Pasteur*, 1911, XXI, p. 492.

<sup>31</sup> Semple, "Sci. Mem. by Officers of Med. and San. Depts.," Gov. Ind., N. S., No. 44.

several days, succumbs at 24 hours at 37° C. According to Cumming<sup>32</sup> 1 per cent. phenol does not destroy the virus in 6 hours, while 2 per cent. solution kills it in less than 24 hours. On the other hand, most of the aldehyd compounds are very active in destroying the infectivity of the fixed virus. A 0.5 per cent. solution of salicylaldehyd, benzaldehyd, or furfural destroys the virus in less than 3 hours. The specific disinfecting action of formaldehyd is shown by the fact that the virus is destroyed when exposed for two hours to 0.08 per cent. solution. This indicates that formalin may be a useful substance to treat dog bites, although experiments have shown that it is not as dependable as nitric acid. Bichlorid of mercury, 1-1,000, for 1 hour, or a saturated solution of iodine in water, completely destroys the virulence, and Wyrskyowski has shown that gastric juice has a pronounced deleterious effect upon the virus.

### PROPHYLAXIS

The prevention of rabies is considered under three heads: (1) Treatment of the wounds; (2) the Pasteur prophylactic treatment, and (3) the control of the disease in dogs by muzzling and quarantine.

The cauterization of the wound and the Pasteur prophylactic treatment are efficient preventive measures for the individual, but they are not the true and best methods of controlling and preventing rabies. The disease may be avoided, even exterminated, by an intelligent system of muzzling and quarantining of dogs. A high tax on dogs and leashing are only restrictive measures. In England, when the dogs were muzzled, rabies diminished. The law was repealed, owing to misplaced sympathy for the dog, and rabies promptly increased. The law was again enforced, and in about two years the disease disappeared (see Fig. 10). A strict quarantine of six months was maintained against dogs entering England, but this was broken by the war and rabies reappeared in England in 1918.<sup>33</sup> Consistent muzzling of all dogs for two years will practically exterminate rabies. In Australia there are few carnivorous animals, mostly marsupials; there rabies does not exist, for it has been kept out owing to early and effective quarantine measures. Norway, Sweden, and Denmark also obtained good results and the same can be done in other peninsular regions.

Prophylactic measures necessary to control the dog question are: the destruction of ownerless dogs; license fee and tag for all dogs; owners to be legally responsible for damage inflicted by their dogs; education of the dog-owning public concerning the spread of communicable diseases, especially rabies; compulsory reporting of all cases or suspected cases of rabies. Further special measures advocated are: muzzling;

<sup>32</sup> *Jour. Infect. Dis.*, XIV, 1, January, 1914, p. 33.

<sup>33</sup> *Br. Med. Jour.*, March 22, 1919, 350, 1.

restraint with chains, leash, etc.; observation in quarantine, or killing of all animals bitten by dogs; disinfection, etc.<sup>34</sup>

# THE LOCAL TREATMENT OF THE WOUND

Wounds produced by the bite of an animal in which there is any suspicion of rabies should at once be canterized with "fuming" or strong nitric acid.<sup>35</sup> The acid is best applied with a glass rod very thoroughly

FIG. 10.—CHART SHOWING RELATION OF ENFORCEMENT OF MUZZLING LAW TO PREVALENCE OF RABIES IN GREAT BRITAIN (the figures in the cross-hatching indicate the number of persons who died of rabies in England and Wales. The ordinates represent cases in dogs). (Straus and Frothingham.)

to all the parts of the wound, care being taken that pockets and recesses do not escape. Thorough cauterization at once reduces the danger of wound complications, and experience demonstrates that wounds so treated at once are practically never followed by rabies. Marie obtained conflicting results with local treatment in experimental rabies; Cabot<sup>36</sup> obtained the best results with nitric acid, and was able to save the lives

<sup>34</sup> In addition to rabies, dogs are responsible for other infections in man, such as hydatids, tapeworms (especially in children), round worms, tongue worms, and also fleas and ticks which transfer from the dog to man and which may in this way transmit diseases and parasites. In animals, dogs are responsible for gid in live stock and cysticerci in sheep, reindeer and live stock.

<sup>35</sup> Sp. gr. over 1.48.

<sup>36</sup> *Medical News*, March, 1899.

of 91 per cent. of guinea-pigs by cauterization with nitric acid at the end of 24 hours; Poor<sup>37</sup> saved 45 per cent., at the end of 22 hours. In the absence of nitric acid, formalin or the actual cautery may be used, but they have inferior prophylactic value. Strong germicides, such as carbolic acid, are not reliable. Nitrate of silver is valueless. In any wound produced by the bite of an animal cauterize with nitric acid unless sure that the animal is not mad.

Experiments made in my laboratory indicate that no substance takes the place of nitric acid, and further emphasizes the importance of cauterizing all portions of the wound, especially the edges of the skin.

It has been shown that the virus may remain alive and virulent in the scar for a long time, and it has become a question whether patients seen after the wound has healed should not have the scar excised and the wound cauterized with nitric acid; this, however, is not the practice.

#### THE PASTEUR PROPHYLACTIC TREATMENT

This method of prophylaxis was announced December 6, 1883, by Pasteur, at the International Congress at Copenhagen, and on February 24, 1884, he laid before the French Academy the details of his experiments and results. The next year Pasteur, with the help of Roux and Chamberland, worked out the details of the method now in general use.

The principle of the treatment consists in producing an active immunity by means of an attenuated virus. The virus is attenuated by drying. The fixed virus contained in the spinal cord of rabbits dead of hydrophobia is the material used, for subcutaneous injection.

**Street Virus and Fixed Virus.**—The distinction between fixed and street virus is of fundamental importance in reference to the question of immunity. Street virus is obtained from mad dogs naturally infected. When this virus is inoculated into a rabbit, it reproduces the disease after a period of incubation of from 14 to 21 days or more. This street virus may then be conveyed from rabbit to rabbit through a number of transfers. In the passage from rabbit to rabbit the virus becomes more virulent for rabbits. The period of incubation is progressively shortened, until finally the rabbits invariably sicken on the sixth or seventh day and die on the ninth or tenth. When the virus has reached this degree of virulence for rabbits, it is said to be "fixed," for the reason that its potency remains constant. In its passage through rabbits the modification from street virus to fixed virus is gradual. It is important to note that fixed virus, which has attained a high degree of virulence for rabbits, has lost much of its virulence for

<sup>37</sup> *Collected Studies*, Research Lab., Dept. of Health, City of N. Y., VI, 1911, p. 25.

dogs, and seems to be avirulent for man when introduced into the subcutaneous tissue.<sup>38</sup>

Ferran in 1888 treated 85 persons for dog bites by injecting the fresh fixed virus subcutaneously, without ill effects. Wysokowicz in 1902 injected 70 persons intravenously without an accident. In institutes using the method of Höyges, many persons have received dilutions of an emulsion of the fresh pons and medulla. Nitsch, Proescher and others injected large amounts of fresh fixed virus subcutaneously without producing symptoms. Proescher, in fact, injected himself with the entire brain and medulla of a rabbit; and another entire brain into a volunteer. No ill effects of any kind were noted. The virus used was shown to be virulent when a small amount of it was introduced under the dura of a rabbit. It is indeed quite difficult to give rabies to animals experimentally by subcutaneous injection. Marx tested the fresh fixed virus upon monkeys in large doses, with negative results. The evidence points clearly to the fact that the fixed virus of rabbits does not produce rabies in man when introduced into the subcutaneous tissue.

**Preparation of the Virus.**—Rabbits are injected under the dura mater with a few drops of an emulsion of fresh fixed virus obtained from the pons or medulla of another rabbit dead of hydrophobia. Strict aseptic precautions are necessary in order to keep out other infections. The rabbit should begin to show symptoms on the sixth or seventh day, and die on the ninth or tenth. Usually the rabbit is not allowed to die, but is chloroformed on the last day in order to avoid terminal infections and unnecessary suffering. The spinal cord is removed and hung in a bottle containing potassium hydroxid. These bottles are kept in the dark at a temperature of 22° C. Under these conditions the cord gradually desiccates, and at the same time the virulence of the virus diminishes, until the fourteenth day, when it is no longer infective. This is why Pasteur started the treatment with a cord fourteen days old. In fact, the virus dies long before the fourteenth day—five-day old cord usually fails to infect.

About one-half a centimeter of the cord constitutes a dose. This is ground in about 2.5 c. c. of sterile salt solution so as to produce a uniform emulsion, which is injected into the subcutaneous tissue of the abdominal wall. In many institutes the small segments cut each day from the drying cord are placed in pure glycerin. The virulence of the cord in glycerin is not altered for at least 30 days, if kept in the dark and at 15° C. This method, introduced by Calmette<sup>39</sup> in 1891, based upon observation made by Roux in 1887,<sup>40</sup> is very convenient, especially

<sup>38</sup> *N. Y. Med. Jour.*, Oct. 9, 1909, also *Arch. of Int. Med.*, Sept., 1911, VIII, 3, p. 353.

<sup>39</sup> *Ann. de l'Inst. Pasteur*, Paris, 1891, Vol. V, p. 633.

<sup>40</sup> *Ann. de l'Inst. Pasteur*, Paris, 1887, Vol. I, p. 87.

where comparatively few patients are treated. Glycerin has the added advantage of destroying infections due to non-spore-bearing bacteria that may be present.

As a further precaution, bacteriologic examinations are made of parts of the spinal cord in order to insure the absence of bacteria, and the rabbit is carefully autopsied as a guarantee that no other disease is present.

**The Scheme of Treatment.**—The scheme of treatment advocated by Pasteur and still used at l'Institut Pasteur in Paris and many other places is shown in the following table:

PASTEUR PROPHYLACTIC TREATMENT—RECOMMENDED BY PASTEUR

Mild Treatment			Intensive Treatment		
Day of Treatment	Age of the Dried Cord	Amount of Injected Emulsion 1-cm. of Cord to 5 c. c. Salt Solution	Day of Treatment	Age of the Dried Cord	Amount of Injected Emulsion 1 cm. of Cord to 5 c. c. Salt Solution
1	{ 14 Days 13	3 c. c. 3	1	{ 14 Days 13 12 11 10	3 c. c. 3 3 3 3

Some Pasteur institutes now use a modified treatment, starting with an 8-day instead of a 14-day-old cord, which is exemplified in the scheme used at the Hygienic Laboratory, Public Health Service. See table on the following page.

The tendency is to hasten the immunity by using only the intensive treatment for all cases, also to start with fresher cord, some using 4-day-old cord for the initial injection. Intensive treatment should always be given for wounds of the face, head, hand and other exposed parts of the body; for multiple wounds; severe wounds; or for wolf, fox, cat and skunk bites.

\* Double dose.

The scheme of Pasteur has been further modified in various ways, depending upon the method used to attenuate the virus. Thus Pasteur attenuated the virus by drying; Babes by heating; Frantzer by the use of bile; Tizzoni and Cattani attenuated the virus in gastric juice. Högyes used fresh material in a diluted suspension; Ferran fresh material and in increasing doses. Cumming altered the virus by dialysis. Harris dried the fresh virus at low temperature, which is used in diluted suspension. Other methods have been used to attenuate the virus, such as glycerin, carbolic acid, mechanical disintegration, and, lastly, antirabic serum. Ferran in Barcelona, Proescher in Pittsburgh, and others inject patients with the unaltered, fresh, fixed virus. The advantages of using the virus as fresh and strong as possible are that an active immunity is produced more quickly, and this is of considerable importance in wounds of the face; also in wolf and cat bites, which frequently have a short period of incubation. Further, fewer injections of the fresh virus are necessary to produce an immunity, and this shortens and simplifies the treatment.

Harris<sup>41</sup> has shown that rabic material may be completely desiccated without destruction of virulence, provided the dehydration takes place at a low temperature. The lower the temperature the greater will be the amount of virulence preserved. Virus so desiccated contains per weight as much infectivity as the fresh virus. The virus thus dried is so stable that it may be standardized, permitting an accuracy of dosage hitherto impossible. The unit is the smallest amount which, when injected intracerebrally into a full-grown rabbit, will produce paresis on the

<sup>41</sup> *Jour. of Infect. Dis.*, May, 1912, X, 3, pp. 369-377.

seventh day. For slight wounds Harris gives seven injections, but for severe injuries he gives two injections a day for twelve to fourteen days.

Treatment at a distance from a Pasteur institute is now practical by sending a piece of cord in glycerin; or the emulsion in glycerin, in a thermos bottle; or the dry material in accordance with Harris' method.

**Care During the Treatment.**—During the treatment the patient may go about his usual business. It is not necessary to stay in bed. The patient should, however, avoid fatigue, cold, emotional stress, trauma, and alcohol. It has been shown that these are important predisposing factors to the disease. It was found that customs' officers returning to the Siberian borders after prophylactic treatment for wolf bites showed an unusual mortality, which seemed to be due to exposure to cold. The disease has been observed to be brought on after a cold bath, falling into the water, and similar depressing influences.

**Complications of the Treatment.**—The Pasteur prophylactic treatment may be complicated by (1) local reactions or (2) paralysis.

*Local reactions* at the site of the wound are usually trivial. Abscesses almost never occur. The local reactions consist of redness and induration. It is not necessarily the last injection, but rather the site of some previous injection that flares up, but soon subsides without further trouble. This occurrence increases with the progress of the treatment; it is most frequent in the second week. As the treatment involves the introduction of a large quantity of foreign proteins into the body, it is probable that these reactions represent a phase of hypersusceptibility. See Anaphylaxis.

*Paralysis.*—Paralysis occurs occasionally and may be fatal. This complication seems to be a mild or modified type of rabies, but there is doubt concerning its cause. There is evidence that it may be due to infection with the fixed virus or possibly to toxin—or both. Serious paralysis is a rare complication; it doubtless occurs in mild form more often than is known. It affects adults chiefly, young children almost never. Simon collected data up to and including 1911, showing the occurrences of 100 instances of paralysis among 217,774 persons treated. In this series there were 19 deaths. The incidence of paralysis seems to vary with different methods of antirabic treatment.<sup>42</sup>

In a case treated at the Hygienic Laboratory the paralysis came on 18 days after treatment, and was transient. H. E. Hasseltine<sup>43</sup> reports two cases of paralysis following antirabic treatment, with one death. The New York Pasteur Institute reports a death from "ascending paralysis," which came on four days after the treatment. W. A. Jones<sup>44</sup> reported two cases with recovery. In 1905 Remlinger, head of the Constanti-

<sup>42</sup>The subject is brought up to date in Fiedler's article in the *Journal of the American Medical Association*, June 3, 1916, LXVI, p. 23.

<sup>43</sup>Public Health Report, July 30, 1915, Vol. XXX, No. 31, p. 2227.

<sup>44</sup>*Jour. A. M. A.*, Nov. 13, 1909, p. 1626.

nople Institute for Rabies, reported 40 cases of paralysis; Babes had 8 cases of paralysis (all mild) in 6,525 treatments; Müller found 16 cases in the literature, and had two of his own; Panpoukis, three cases; Jones, 2. Mejio <sup>45</sup> reported 19,800 cases treated in the Pasteur institute, Buenos Aires, of whom 24 developed paralysis, with 4 deaths. One instance was a child of six, apparently healthy a month after the Pasteur treatment. He then had a fall from a hammock; the next day his legs were paralyzed; the paralysis proved of the ascending type, fatal in two weeks.

**The Immunity.**—*Duration.*—The immunity appears two weeks after the treatment and lasts a varying period of time, depending upon the individual—at least for several years. In this respect it does not differ from other instances of acquired immunity. The Pasteur prophylactic may be repeated in persons bitten a second time. The lower animals may also be protected. The fact that the immunity appears on the fifteenth day after the last treatment was discovered by Pasteur as a result of animal experimentation. The statistics of the Pasteur Institute, giving the mortality from rabies in persons following the prophylactic treatment, exclude instances in which the disease develops within fifteen days after the last prophylactic injection.

*Nature.*—The nature of the immunity is not clear. It certainly is not due to an antitoxin. Immune bodies are demonstrable in the blood twenty days after the last injection. The activity of the virus can be neutralized by mixing it in vitro with the blood serum of an immunized animal. This neutralization is generally considered to be microbicidal or lytic in nature.

*Degree.*—The degree of the immunity also varies, as is evidenced by the fact that a certain small percentage of the persons treated die of rabies.

**The Results of the Treatment.**—Statistics giving the results of the treatment are somewhat difficult to analyze, as many factors are unobtainable. Patients should be kept under observation at least a year. Exceptional cases occur one year following exposure. Cases that occur within fifteen days after the treatment are excluded from the French statistics, for reasons that have already been stated. The figures on this basis show a mortality of less than 0.5 per cent. Better results are being obtained from year to year.

The table on the following page gives the general results at l'Institut Pasteur, Paris, since beginning the treatment.

When we compare these figures with the fact that from 6 to 10 per cent. and sometimes 16.6 per cent. of all persons bitten by rabid dogs die of rabies, the prophylactic value of the Pasteur treatment is evident.

Faber found 27 deaths out of 339 persons bitten by mad dogs; Kurrimoto, 17 per cent. in Nagasaki; Babes, 15 per cent. of 995 in Hun-

<sup>45</sup> *Semana Medica*, Buenos Aires, XXIV, No. I, p. 10.

## RESULTS OF TREATMENT AT L'INSTITUT PASTEUR, PARIS

Year	Persons treated	Deaths	Mortality	Year	Persons treated	Deaths	Mortality
1886	2,671	25	0.94%	1903	628	2	0.32%
1887	1,770	14	0.79	1904	755	3	0.39
1888	1,622	9	0.55	1905	727	3	0.41
1889	1,830	7	0.38	1906	772	1	0.13
1890	1,540	5	0.32	1907	786	3	0.38
1891	1,559	4	0.25	1908	524	1	0.19
1892	1,790	4	0.22	1909	467	1	0.21

1901	1,321	5	0.38	1918	1,803	3	0.16
1902	1,005	2	0.18	1919	1,813	3	0.16

gary; Horsley's figures are 15 per cent. Some series of cases give a much higher mortality. Thus, of 855 persons bitten by mad dogs, collected by Tardieu, Thamehayn, and Bouley, 399 ended in death, or 46.6 per cent. In another series of cases given by Bouley, out of 266 persons bitten by mad dogs, 152 died of hydrophobia. But of these 120 were bitten on the face and hands, the greater danger of which has been mentioned. The mortality resulting from bites of wolves is placed by Babes at from 60 to 80 per cent.

**Contraindications.**—There are no known contraindications to the treatment. All ages and conditions should be treated if exposed. Apparently no harm is done pregnant women. I have injected patients having malaria without trouble following. The treatment may be continued in patients having colds, fevers, and other ailments without noticeable harm.

**When to Give the Pasteur Prophylactic.**—It is sometimes difficult to decide whether the Pasteur prophylactic treatment should or should not be given. Treatment causes sufficient personal inconvenience, not to speak of the danger (however slight) of paralysis, to avoid advising it if unnecessary. In many cases it is impossible to discover whether the dog that inflicted the bite is mad or not. The rule in cases of doubtful exposure is to advise the treatment.

Persons who apply for treatment of dogbites fall into one of the five following categories with reference to the Pasteur prophylactic:

(1) The dog is mad or shows suspicious symptoms: In this case, begin treatment at once.

(2) The dog is not mad: Observe it carefully for ten days, and if no symptoms develop, there is no danger of rabies in the person bitten. The treatment is therefore unnecessary. (The dog may nevertheless develop rabies after ten days and if it has been bitten by another dog should be kept in quarantine for six months.)

(3) The dog is not identified: This is a common occurrence, especially with children. The rule in such cases is to advise the Pasteur prophylactic treatment, except in places known to be free of rabies.

(4) Exposure to saliva: Persons not infrequently apply for advice giving the following history: They have not been bitten, but they have been licked on the hands and face by a dog that subsequently was discovered to have the disease. Persons are sometimes similarly exposed by washing the mouth of a rabid horse. In these cases the important question is whether there were fissures or abrasions in the skin at the time. There may be little wounds in the skin not evident to the naked eye. It is possible to infect animals by rubbing the virus on the shaved skin. The rule is therefore to advise the protection which the treatment affords in persons thus exposed.

(5) In psychoneurotic patients with a distressing phobia of rabies, it may afford comfort to give a mild course of treatment as much for its psychotherapeutic effect as for specific immunity.

*The Dog.*—In all cases it is important to know whether the dog is mad or not. If the dog can be found and kept under observation for 10 days and no symptoms appear, the Pasteur treatment is not necessary. Animals killed early in the course of rabies may fail to show the microscopic evidence of the disease, thus causing an indefinite delay in diagnosis awaiting inoculation tests. Dogs that have bitten persons should not be summarily killed, but should be apprehended and turned over to the proper authority; if killed, the head should be sent to the nearest diagnostic laboratory. Should the dog develop symptoms, the question of diagnosis is all-important.

**Diagnosis of Rabies in Dogs.**—The diagnosis of rabies in dogs may be made in four ways: (1) from the symptoms; (2) from the presence of Negri bodies in the central nervous system; (3) from the lesions in the peripheral ganglia, and (4) by animal inoculations.

1. The *symptoms* may be very suggestive, but a diagnosis must always rest upon the pathological lesions and the inoculation tests. The course of the disease may be divided into three stages: (a) a premonitory stage, (b) a stage of excitement, and (c) a paralytic stage. The first two stages may be absent or transient. All rabid animals invariably become paralyzed before they die. In dogs the first symptom consists solely in a change in the disposition of the animal. He is easily excited, but does not show a tendency to bite. Soon the restlessness becomes more marked, and the animal may become furious and even show signs of delirium. The dog does not fear water, as is commonly supposed, but rushes about attacking every object in his way. Dogs suffering from furious rabies have a tendency to run long distances (25 miles or more), often biting and inoculating large numbers of other animals and persons en route. Very soon paralysis sets in, commencing in the hind legs, and

finally becomes general. The course of the disease is always rapid, averaging from 4 to 5 days, rarely exceeding 10 days. When the stage of excitement is brief or absent, the disease is known as dumb rabies.

2. There is a difference of opinion concerning the significance of the Negri bodies (*Neurorrhycles hydrophobiae*), which, however, are very constant in rabies and peculiar to it. If Negri bodies are found in the dog, the Pasteur treatment should be started at once. The absence of Negri bodies, however, does not necessarily mean the absence of rabies. These bodies are sometimes difficult to find, or may not be present in the parts of the central nervous system which are examined. Negri bodies are found especially in the horn of Ammon and the cerebellum; they are 1 to 23 micra in diameter; usually round or oval; strongly eosinophilic; occur within and without the nerve cells; and sometimes contain a nucleus (?). Owing to their resemblance to red blood cells, the finding of Negri bodies *within* the cells is the safest criterion. The diagnosis may thus be established in about 90 per cent. of cases.

Negri bodies for diagnostic purposes are best demonstrated by impression preparations of Ammon's horn and cerebellum, stained according to Van Giesen as recommended by Frothingham or stained by Bond's modification of the Mann stain. Impression preparations are made by gently pressing a microscopic slide upon the cut surface of Ammon's horn and the cerebellum and lifting with a quick movement. Care should be taken to obtain thin uniform impressions because thick impressions do not show differential staining for Negri bodies. Pieces of the Ammon's horn and the cerebellum selected for impressions should be from four to six millimeters thick. Three or four impressions to a single slide should be made from each piece of the Ammon's horn and cerebellum. Four or five pieces of each Ammon's horn and the same number from the cerebellum are sufficient. The impression preparations obtained in this way show the characteristic arrangement of the cells of the hippocampus and of the cerebellum and rarely fail to contain the Negri bodies in infected material. When the brain is badly mutilated or decomposed, impressions taken from any of the available material containing gray matter will frequently show the Negri bodies if infected.

To stain impression preparations as recommended by Frothingham the following slightly modified procedure is given: (1) Fix before the impression dries in methyl alcohol for five minutes; (2) stain at room temperature with Van Giesen, while still moist with alcohol, for eight to ten minutes; (3) wash thirty seconds with running tap water; (4) blot with filter paper. The Van Giesen stain is made as follows: Tap water 20 c. c. to 50 c. c.; saturated alcoholic fuchsin (f. Bac. Grubler) 1 drop; saturated aqueous solution methylene blue (f. Bac. Koch Grubler) one to ten drops. The amount of tap water and the

amount of methylene blue required for good differentiation vary with different stock solutions of the stains. This stain changes little in three to four days.

To stain by Bond's modification of the Mann stain proceed as follows: (1) Fix before the impression dries in methyl alcohol five to six minutes; (2) wash thirty seconds with running tap water; (3) stain for four to five minutes with a mixture consisting of 1.0 c. c. of 1 per cent. aqueous eosin (Eosin W. gelbl. Grubler), 0.7 c. c. to 1.0 c. c. of 1 per cent. aqueous *methyl* blue (Grubler) and 6.0 c. c. of distilled water; (4) wash with running tap water for thirty seconds; (5) blot with filter paper; (6) dehydrate with absolute alcohol; (7) clear with a mixture consisting of one part of xylol and two parts of aniline oil; (8) wash with xylol; (9) mount in balsam. The Mann stain should be freshly prepared each time it is used. In practice it is better to stain by both methods because each has its advantages and disadvantages. The Mann's stain gives definite Negri bodies but the differential staining between the red blood corpuscles and Negri bodies is not always clear. With the Frothingham method Negri bodies can hardly be mistaken for anything else but the stain itself may be capricious in action and shows relatively fewer Negri bodies.

3. The lesions of Van Gehuchten and Nélis, described in 1900, are the most characteristic anatomical changes. These lesions are found late in the disease in the peripheral ganglia of the cerebrospinal and sympathetic systems, especially in the plexiform ganglia of the pneumogastric nerve, and the Gasserian ganglia. The normal nerve cells of these ganglia lie in a capsule lined with a single layer of endothelial cells. In rabies these endothelial cells proliferate and the nerve cells may be partly or entirely destroyed and replaced by diverse cells associated with chronic inflammatory processes. In addition, lymphatic infiltration also occurs about the sheaths surrounding the individual nerve cells. Either the proliferative or infiltrative changes may predominate. In order to find these lesions, it is necessary to fix the ganglia in Zenker's fluid and to stain the sections by the eosin-methylene blue method. This method of diagnosis is available in only a small percentage of cases.

4. The final diagnosis of rabies rests upon animal experimentation. A small quantity of an emulsion of the medulla or pons of the suspected animal is placed under the dura mater of a rabbit or guinea-pig. The diagnosis by this method, however, requires so much time (on account of the long period of incubation of the disease) that it is of no practical value in deciding whether or not the Pasteur prophylactic treatment should be given, but in any critical case the positive evidence furnished by animal experimentation is incontrovertible.

If the inoculated rabbit shows no symptoms in one month, and Negri

bodies were not seen in the specimen, then a negative diagnosis may be given, although it is customary to observe the animal for six months.

#### VENEREAL DISEASES<sup>46</sup>

As a danger to the public health, as a peril to the family, and as a menace to the vitality, health, and physical progress of the race, the venereal diseases are justly regarded as the greatest of modern plagues, and their prophylaxis the most pressing problem of preventive medicine that confronts us at the present day.

No serious attempt was made by the sanitary authorities of any of our great cities to deal with this problem until New York City in

<sup>46</sup> Objection has been made to the stigma implied in the term venereal diseases, for these infections are not always transmitted in venery and are often contracted innocently. Syphilis and gonorrhea, however, are unlike other communicable diseases in that they do involve a moral principle. Gonorrhea or syphilis contracted innocently is usually only one remove from promiscuity.

Only one venereal disease among the lower animals is known,—dourine, a syphilis of horses caused by a trypanosome.

1912<sup>47</sup> determined to treat the venereal diseases as any other highly communicable and preventable infection, dealing purely with the sanitary features of the problem from a public health standpoint, ignoring the social and moral phases. The opposition to such activity is slowly being broken down. Progress against the venereal diseases is a repetition of the warfare along other lines of sanitation and hygiene. It is the history of a continuous struggle carried on in the name of law, religion, personal rights, or expediency. Although the difficulties in this case are much greater than in any other group of diseases, an intelligent and persistent campaign must end in a long-delayed success.

Biggs states that in 1912 at least 800,000 people, or more than one-fifth of the adult population of New York City, have, or have had, some venereal disease, and that in a large percentage of these persons the disease is still active. The number of new infections occurring each year probably exceeds that of all other notifiable diseases combined. In view of such figures the magnitude and the importance of the problem of administrative control, as applied to these diseases, become clearly apparent.

The venereal diseases are a constant menace to the clean living public as well as to the licentious. The history of preventive medicine can present no greater tragedy than the home invaded by syphilis or gonorrhea.

There are three venereal diseases: syphilis, gonorrhea, and chancroid. In order to have a clear understanding of the problems of venereal prophylaxis it is necessary to have a knowledge of the essential features of these preventable infections. Two of them, syphilis and gonorrhea, are of great importance, because they are very prevalent and because they are very serious infections with grave consequences. Gonorrhea is the great preventer, syphilis the great destroyer of life.

### SYPHILIS

Syphilis is a specific infection caused by the *Spirochæta pallida*.<sup>48</sup> It is acquired by direct contact with infected persons, by inoculation with infected things, and by congenital transmission. Syphilis runs a chronic course with lesions and symptoms of extraordinary diversity. The initial lesion or chancre forms on the skin or mucous membrane at the site of entrance of the spirochetes. The period of incubation is never less than 10 days, with a maximum of 90 days. In the majority of cases, the chancre appears between the 14th and 40th days.

There are many striking things about syphilis, but nothing so striking as its persistence in spite of knowledge complete enough to stamp

<sup>47</sup> Resolutions adopted by the Board of Health, February 20th.

<sup>48</sup> Also known as *Treponema pallidum*.

it out and in view of the popular dread in which the disease is held. It is preventable, even curable—yet scarcely another disease equals it in the extent and intensity of its ravages. It is the great canker of humanity.

Syphilis is a good illustration of the fact that it is much more difficult to control a disease transmitted directly from man to man than a disease transmitted by an intermediate host, or one in which the virus is transferred through our environment. We have a certain amount of control over our surroundings, and we have dominion over the lower animals, but the control of man requires the consent of the governed.

Civilization and syphilization have been close companions, but syphilis is now less prevalent among civilized than uncivilized peoples—this is promising. Civilization, however, should not be content until it has controlled syphilis as effectively as it has some other preventable infections. The effort to do so, at least, must be persistent and sincere.

From the economic side syphilis is not a serious disease in its primary and secondary stages; that is, persons with syphilis during the early stages are usually not ill enough to cease work.<sup>49</sup> Acutely fatal cases, such as frequently occurred in the sixteenth century, are now rare; in other words, the disease has lost much of its early virulence. It is the late manifestations, or the so-called parasyphilitic lesions, as well as the inherited consequences of the disease, that play havoc. About one-fifth of all the insane in our asylums are cases of general paresis; 90 per cent. of these give the Wassermann reaction. Syphilis, alcohol, and heredity fill our insane asylums, jails and almshouses.

The consequences of syphilis are often more severe upon the offspring than upon the syphilitic parent. The infection itself, or various defects, especially of the nervous system, resulting from the consequences of syphilis, may be transmitted from parent to child, often with fatal results. When death does not ensue the results may be still more tragic.

The health officer should regard syphilis just as he does the acute febrile exanthematous diseases. Because syphilis runs a slow and often chronic course with mild constitutional symptoms during its early stages, it is often placed in a class by itself. This is a mistake. Syphilis has its period of incubation, eruption, and decline, just as measles and smallpox have.

**Historical.**—There is an accurate historical record of the startling spread of syphilis over the known world in a few years after 1495, and from that time it has everywhere been endemic. No similar record exists of the sudden establishment of any other great disease among the larger part of the earth's inhabitants. Evidence, however, points to the severe character of the disease during this early epidemic, the cases often run-

<sup>49</sup> But it is most communicable during this time.

ning an acute, febrile course, accompanied by symptoms of such severity as are now seen only occasionally. Syphilis was unknown before the year 1493. It is said to have been brought by the crew of Columbus, on his first voyage from Española, or Hayti.<sup>50</sup> Some of the returning crew accompanied Charles VIII of France in the autumn of 1494 with the army, 32,000 strong, which invaded Italy for the conquest of Naples. The epidemic began in Italy at this time, and the disease spread quickly over Europe with the scattering of the troops. At first the French called it the Neapolitan disease, and the Italians called it the French pox, or Morbus Gallicus. The name of the disease was taken from a popular poem written by Fracastor in 1530 entitled, "Syphilis sive Morbus Gallicus," in which the symptoms are clearly described in the principal pastoral character—Syphilis.

In 1903, Metchnikoff and Roux<sup>51</sup> transmitted the disease to lower animals and demonstrated the prophylactic value of calomel inunctions, and also opened up a rich field of animal experimentation. In 1905, Schaudinn<sup>52</sup> discovered the cause and thus made diagnosis certain. In 1906, Wassermann, Neisser and Bruck<sup>53</sup> introduced the indirect method of diagnosis by serum reaction. In 1910, Ehrlich,<sup>54</sup> after many years of experiment, gave to the world salvarsan, a specific, synthetic spirocheticide. In 1911, Noguchi<sup>55</sup> cultivated *Spirochæta pallida* outside of the body and prepared luetin. In 1913, Noguchi<sup>56</sup> demonstrated the spirochetes in the brain of paretics and in the cord of a tabetic. This unparalleled group of achievements, all the result of scientific work in laboratories, in 10 short years threw light upon the cause, mode of transmission, pathology, treatment and prevention of the disease.

**Prevalence.**—The percentage of syphilitics in the population at large is difficult to determine. It is commonly estimated at about 8 per cent. The amount of infection in certain groups is given by Vedder as follows: Prostitutes, 50 to 100 per cent.; tuberculous in institutions, 20 to 30 per cent.;<sup>57</sup> sick children in hospitals, 2 to 10 per cent.; mentally backward and idiots, 20 to 40 per cent.; criminals, 20 to 40 per cent.; presumably healthy men of the class that enlist in the regular army, 20 per cent.: this group represents unskilled labor and a certain percentage of the tradesmen. Among men of better families the per-

<sup>56</sup> Jour. Exp. Med., 1913, XVII, p. 232.

<sup>57</sup> The prevalence of syphilis among the tuberculous in this country has been variously placed by different investigators on the basis of a clinical examination or a positive Wassermann, or both. Some of these are as follows: Vedder, 23.2 per cent.; Snow and Cooper, 20 per cent.; Petroff, 21.8 per cent.; Lyons, 9.2 per cent.; Jones, 29 per cent.

centage varies from 2 to 10 per cent., depending upon age, marital condition and other factors. Among young women in the community, the percentage of syphilitic infections fluctuates between 3 and 20 per cent., depending upon age, marital condition, education and social status. As among men, the proportion of infections increases as we descend in the social scale. It is estimated that the rates for the colored race are at least double those for the white race. See also page 73.

**Stages of the Disease.**—Syphilis is divided into four stages which are not always well defined in time or sequence.

*The chancre.*—The *primary stage* consists of the chancre which forms at the site of the initial infection. The regional lymph node becomes enlarged and hard. The typical Hunterian chancre is an indurated and undulated ulcer in the skin or mucous membrane, and appears about three weeks (not less than ten days) after the receipt of the infection. It is usually single and painless, but frequently is atypical, and may be but a trifling lesion. In the absence of a careful daily inspection, it may exist many days before it is detected, or even escape notice altogether.

The chancre contains many spirochetes which may readily be seen with the dark field illumination. This is the best method of early diagnosis. The Wassermann reaction usually does not become positive until from two to six weeks after the appearance of the chancre. It is important to examine every sore on the genitalia for spirochetes, for the initial lesion of syphilis often resembles a chancroid, sometimes only a simple abrasion. Mixed infections are frequent.

The *secondary stage* is determined by a general invasion of spirochetes throughout the system, and is characterized by involvement of the lymph nodes, eruptions upon the skin and mucous membranes, fever, anemia, and other indications of a generalized infection.

The *third stage* is characterized by a localized granulomatous growth known as a gumma. Gummata may appear in almost any tissue or organ of the body.

A *fourth stage*, consisting of inflammatory and degenerative lesions of the heart, blood vessels and central nervous system, is often added to the picture, and occurs long years after the primary sore. This stage, formerly regarded as sequelae or parasymphilitic phenomena, is now known to be associated with spirochetes, and should be classed as a stage of the disease. This is the most serious and disabling stage of the disease and is a frequent cause of insanity or premature death. Examples of the chief manifestations of the late stage of syphilis are locomotor ataxia and dementia paralytica, also arteriosclerosis, aneurism, cerebrospinal syphilis, etc. The prevention of these serious conditions depends upon early recognition of the chancre, followed by prompt and thorough treatment.

**Fatality.**—Syphilis is the chief cause of death in early adult life in persons otherwise hale and hearty.

If it be remembered that syphilis is the real cause of death in all cases of general paresis, locomotor ataxia, and aortic aneurysm, in many cases of apoplexy, and is a contributory cause of death in a host of other conditions, including many cases of pulmonary tuberculosis, the real influence of syphilis on the mortality rate begins to be suspected. Osler some time ago made the statement that "of the killing diseases, syphilis comes third or fourth." But recently from an analysis of the Registrar General's statistics for 1915, he estimates the actual deaths from syphilis in England and Wales at about 60,000, thus moving syphilis to the top of the list. Leredde estimates that syphilis probably kills 25,000 persons each year in France.

According to Lenz,<sup>58</sup> in the large cities, 25 per cent. of syphilitics die as the result of endarteritis (angina pectoris, aortic insufficiency, aneurysm), while 3 or 4 per cent. of syphilitics die from general paralysis, 1 or 2 per cent. from tabes and at least 10 per cent. more as the result of syphilitic lesions of the brain, liver and kidneys. Almost half of all syphilitics eventually succumb as the result of their infection. Syphilis is therefore the greatest cause of premature death of men in large cities.

Mattauschek and Pilcz<sup>59</sup> found that of 4134 officers of the Austrian Army who contracted syphilis between the years 1800-1900, on January 1, 1912: 198 had general paralysis; 113 had locomotor ataxia; 132 had cerebrospinal syphilis; 80 suffered from different psychoses; 17 died of aneurysm; 147 died of tuberculosis; 20 died with syphilis designated as the cause; 101 developed myocarditis and arteriosclerosis, 86 of whom died from this condition.

**Diagnosis.**—Early diagnosis and prompt treatment are the most practical and promising measures to control syphilis (page 85). The clinical symptoms are often atypical and elusive; reliance on laboratory tests is therefore imperative.

*Dark field illumination* should be applied as a routine to every genital sore, by an expert. A single negative finding is not conclusive, and should be repeated daily for several days. No local antiseptic should be applied until the diagnosis is established. One application of a spirocheticide, such as silver nitrate, mercury, copper sulphate, iodine or iodoform, is often sufficient to cause the disappearance of the spirochetes from the surface of the sore.

*The Wassermann reaction* becomes positive only after a general invasion of the spirochetes takes place. At the time of the first appear-

<sup>58</sup> *Ueber die Häufigkeit der syphilitischen Sklerose der Aorta relativ zur gewöhnlichen Athero-sklerose und zur Syphilis überhaupt*, *Med. Klinik*, 1913, IX, 955.

<sup>59</sup> *Med. Klinik*, 1913, IX, 1544; also *Berl. Klin. Wchnschr.*, 1908, XLV, 1213.

ance of the chancre this reaction is invariably negative. It appears by the tenth day in about 30 per cent. of cases, and is positive in 96 per cent. of all cases by the 40th day. The Wassermann reaction therefore cannot be depended upon for early diagnosis, but soon becomes the most reliable laboratory test. It (see also p. 65) should be remembered, however, that in a small percentage of syphilitics, the Wassermann reaction remains negative, while on the other hand it may become positive in other infections, such as yaws, and sometimes in tuberculosis, malaria, pneumonia, scarlet fever, and especially in diseases associated with deranged metabolism of the liver. We must be cautious in drawing conclusions from positive Wassermans in other diseases, for it is often difficult to rule out syphilis.

The *luetin test* is an anaphylactic reaction depending upon sensitization of the skin. It does not always appear, and then late in the disease. It is more useful in prognosis and as a guide to treatment than in diagnosis.

**Methods of Transmission.**—Syphilis is transmitted directly, indirectly, and congenitally.

In a large majority of all cases of syphilis, the infection is transmitted during sexual approach and usually as a consequence of adulterous relations. It is, therefore, spoken of as a venereal disease; many cases, however, are contracted out of venery. These innocent infections are more common than is ordinarily supposed. The spirochete is an animated corkscrew and can probably penetrate the unbroken mucous membrane and perhaps the skin, although a fissure or slight abrasion is the site of most chancres.

**Marital Syphilis.**—The subject is of great interest and importance because marital syphilis is so frequent, and because the individual so infected is an innocent victim of the disease, and usually remains ignorant of the infection, and therefore receives little or no treatment. The transmission of syphilis from wife to husband is comparatively rare. On the other hand, the transmission of disease from husband to wife is comparatively common. M. Dechambre says, "Syphilis is divided among husband and wife like the daily bread."

**Extragenital Chancres.**—Extragenital chancres constitute from 5 to 10 per cent. of the total infections with syphilis. Metchnikoff reports that a great number of cases of non-venereal syphilis occurs among children in Russia, where peasants live huddled together and in ignorance. Genital syphilis is not necessarily due to immorality, since it frequently results from marital relations, and has occasionally followed the rite of circumcision. Extragenital chancres are usually acquired innocently but may be the result of improper practices. It is particularly desirable to make this distinction from the public health standpoint, as the measures taken to prevent syphilis resulting from immorality and syphilis

acquired accidentally are naturally quite different. Innocent syphilis, however, is generally the result by one or two removes of syphilis acquired by promiscuity.

Bulkley,<sup>60</sup> Munchheimer, and Fournier<sup>61</sup> have collected from the literature 20,000 cases of extragenital chancre; Schener<sup>62</sup> has analyzed 14,590 of these in regard to location: 3880 occurred on the lips, contracted mainly by kissing; 2144 on the arm, caused by the old-fashioned arm-to-arm vaccination; 1569 occurred on the breast, mainly of healthy wet nurses from syphilitic infants; 1104 on the tonsils; 897 on fingers and hands, chiefly of physicians, nurses and midwives; 753 were caused by circumcision, 181 by cupping, and 109 by tattooing.

*Kissing*.—It is difficult to treat this subject seriously, and yet it must be considered as the most important single method by which accidental syphilitic infection is transmitted. When the public understands that not only syphilis, but also pneumonia, influenza, common colds, sore throats, measles, scarlet fever, whooping cough, diphtheria, and many other infections may be transmitted through kissing, the practice will become automatically reduced to normal and proper limits. The danger from kissing is great when there are mucous patches or other open lesions upon the mucous membrane of the mouth. The kissing party reported by Schamberg<sup>63</sup> has become classic: Eight individuals acquired chancres of the lip from kissing a young man who also had a chancre of the lip. The percentage of infection was very high—eight were infected, only five or six escaped.

*Indirect Transmission*.—The list of articles that have conveyed the contagium by indirect transmission is comprehensive and includes towels, clothing, razors, handkerchiefs, surgical and dental instruments, pipes, et cetera; a considerable number of infections have been traced to barber shops, drinking glasses, and minor operations.

- Congenital and hereditary transmission of syphilis, see p. 645.

**Infectiousness of Lesions and Tissues**.—The *chancre* is highly infectious from its first appearance until it is completely healed. Hence the importance of early diagnosis and prompt treatment.

*All secondary lesions* are potentially infectious because spirochetes have been demonstrated in all of them. The mucous patch is the secondary lesion most commonly responsible for the transmission of the disease. Like the chancre, it fairly teems with spirochetes, it is comparatively painless, and occurring on the mouth or genitalia it occupies the two regions of the body most commonly brought into close and intimate contact with persons of the opposite sex. The vast majority of

<sup>60</sup> *Syphilis in the Innocent*. Bailey and Fairchild, New York, 1894, p. 197.

<sup>61</sup> *Les Chancres Extragenitaux*. Paris, 1897.

<sup>62</sup> *Die Syphilis der Unschuldigen*, Berlin, 1910, Urban and Schwarzenberg.

<sup>63</sup> *J. A. M. A.*, 1911, LVII, p. 783.

infections are acquired from syphilitics in the primary or early secondary stages of the disease. Nevertheless, we must regard any uncured syphilitic as a possible source of infection. The secondary stage with its endless lesions may last for 29 years.

*Tertiary lesions* are infectious, although it was thought for many years that they were not. Practically, cases of infection from tertiary lesions are comparatively rare and only occur from late eruptions of the skin and superficial gummatous ulcerations.

The infectiousness of the *blood* has been demonstrated in all stages of syphilis, but the danger from this source is slight. An exception to this statement is to be noted in the case of surgeons, physicians, nurses, dentists and midwives, among whom syphilis is the great occupational disease.

The *milk* of a syphilitic woman must be regarded as infectious, since it is well known that a syphilitic wet nurse without lesions will almost surely infect a healthy child; the spirochetes therefore appear to be transmitted in the milk.

*Spermatic fluid*.—Warthin's findings<sup>64</sup> demonstrate that the seminal fluid from many secondary cases is infectious, and we may assume that the seminal fluid from tertiary cases may be infectious in the presence of a suitable lesion in the testicles, and this is confirmed by clinical experience, which indicates that some cases of syphilis appear to be transmitted in this way.

*Spinal fluid* is infectious in many cases in which the central nervous system is involved. The *sputum*, *sweat* and *urine* are generally believed not to be infectious, except in the presence of discharging lesions.

For public health purposes, a person suffering from syphilis is considered to be in an infective stage so long as he shows any symptom or lesion of primary or secondary syphilis, or any discharging lesion of the tertiary stage.

**Viability**.—The spirochete of syphilis is a frail organism, yet it may live long enough on towels, glasses, razors, dental instruments, pipes, and other objects to command hygienic respect. Thus, Zinsser and Hopkins<sup>65</sup> found that pure cultures lived 11½ hours on a moist towel. Dried on covered slips, the spirochete failed to grow after one hour. Bronfenbrenner and Noguchi<sup>66</sup> found that the viability of the spirochete is markedly diminished by lack of nutritive substances, presence of oxygen, effect of light, and the toxic effect of sodium chlorid. Gastou and Comandon<sup>67</sup> recovered living and active spirochetes from drinking glasses up to half an hour after they were deposited on the glass.

<sup>64</sup> *Am. Journ. Med. Sci.*, 1916, CLII, p. 508.

<sup>65</sup> *J. A. M. A.*, LXII, 23, June 6, 1914.

<sup>66</sup> *Jour. Phar. and Exp. Therap.*, March, IV, 4, pp. 251-362.

<sup>67</sup> *Bull. de la Soc. Franc. de Dermat. et Syph.*, 1908, XIX, 292.

Hertmanni<sup>68</sup> found that the spirochete lost its motility as soon as drying occurred. Neisser<sup>69</sup> also determined that the virus from syphilitics that produced syphilis when inoculated into monkeys absolutely lost its power to transmit infection as soon as the fluid which contained the organism was dried. We may therefore regard it as demonstrated that any material that has dried has lost its power to transmit the infection. These facts are in accordance with clinical experience, which indicates that infection by indirect contact is through a brief period of time or a short interval of space. Any object recently soiled or still moist with infectious secretions from a syphilitic must be regarded as a possible source of infection.

The *Spirochæta pallida* may retain its life and infectious properties for long periods in tissues that are excised from the body and in various bodily fluids when kept in the laboratory under suitable conditions or in cultures.

**Immunity.**—There is no natural immunity to syphilis and probably no true cure without specific treatment. The disease is much milder now than it was in the 16th century. This indicates that either the spirochete has lost some of its earlier malignancy, or the human race has become more resistant through syphilization. A similar phenomenon is seen in malaria and some other infections caused by animal parasites.

Syphilis confers no definite immunity. Second infections may take place after cure. Chancres are not auto-inoculable, but it is now known that a second chancre can be produced if the inoculation from the first chancre is made soon after its appearance. In other words, super-infection cannot take place when the disease is once established. This indicates a kind of "immunity" while the living spirochetes are in the body. The same sort of resistance is found in leishmaniasis and other parasites belonging to the animal kingdom. Inability to produce super-infections is also seen in active tuberculosis and some other diseases.

The Wassermann reaction is not an index of immunity. If the luetin test becomes negative after having been positive, it is an indication that resistance has disappeared and such persons are susceptible to reinfection.

The hereditary and congenital transmission of syphilis is discussed on page 645

**Syphilis and Life Insurance.**—Syphilis lowers the standard of health and paves the way for other diseases. Whatever the etiological relationship may be, it is definitely known that syphilitics are prone to die early from affections of the heart and vessels, general paresis, diseases of the central nervous system (locomotor ataxia), chronic nephritis, arteriosclerosis, aneurysm, apoplexy, etc. The actuaries of all life insurance

<sup>68</sup> *Ztschr.*, 1909, XVI, 633.

<sup>69</sup> *Arb. a. d. k. Gsndhtsamte*, 1911, XXXVII.

companies know that the morbidity and mortality rates among syphilitics are very much higher than those of any other class of individuals of the community who enjoy apparent good health at the time of examination. The actuaries of a German life insurance company estimate that the mortality ofluetics is 130 to 100 for normal individuals, and in the 36- to 50-year period the average mortality in syphilitics is doubled.

Most insurance companies refuse to accept syphilitics at all. Some companies require extra premiums to compensate for the extra risks. A few companies will accept exceptionally favorable cases who have had a thorough course of treatment and who have shown no symptoms for from 3 to 5 years, but under these circumstances only special policies are issued which do not keep the applicant on the companies' books after 55 years of age.

**Marriage and Syphilis.**—Fournier thought that, with few exceptions, syphilis constitutes only a temporary bar to marriage. As a result of his experience, he concluded, in 1880, that marriage should be prohibited to every man having syphilis which was transmissible, and that it ought to be permitted in men in whom the disease was in such a condition as not to be transmissible. It is impossible, however, to insure any guarantee of safety whatever except in the presence of a definitely established cure.

Finger's rules as modified by Vedder<sup>70</sup> are as follows:

1. A mild normal course of the disease.
2. An efficient course of treatment with both salvarsan and mercury in accordance with the best practice in the treatment of syphilis.
3. An interval of at least four full years between infection and marriage.
4. An interval of three years from the last syphilitic manifestation to marriage with careful observation to determine the existence of symptoms.
5. A negative Wassermann reaction just before marriage, best confirmed by a test at a second laboratory to insure accuracy.

Osler states that the family physician should insist upon the necessity of two full years elapsing between the date of infection and the contracting of marriage. This, it should be borne in mind, is the earliest possible limit, and marriage should be allowed only if the treatment has been thorough and if at least a year has passed without any manifestation of the disease.

It is clear that the great burden of responsibility must be borne by the family physician. It is his duty to warn the patient that marriage may not be absolutely safe, that he must watch for small erosions on the genitalia or in the mouth, that may affect his wife. The

<sup>70</sup> Vedder's "Syphilis and Public Health," p. 209.

family physician should know the facts so that he can watch both wife and children, and afford prompt treatment should it become necessary.

It is not practical to prevent the marriage of many syphilitics by law, although legislation making syphilis a bar to marriage has been enacted by several states.<sup>71</sup> Such laws in practice enable the state to step in after the fact, and while of interest in divorce proceedings, must be regarded as of limited public health usefulness.

The family is the sanitary unit, and it is of fundamental importance to public and private health to protect the sanctity of the home. There is also truth in Hutchinson's<sup>72</sup> contention "that counsels of perfection are often not trustworthy in practice."

**The Wassermann Reaction and Marriage.**—Assent to matrimony should be withheld from individuals with a positive Wassermann test. On the other hand Keyes<sup>73</sup> concludes that a negative Wassermann is not sufficient evidence of the cure or absence of syphilis. Again, a positive Wassermann, unsupported by clinical evidence, may not be sufficient evidence of the presence of syphilis, and therefore in itself does not prohibit matrimony. A fixed, positive Wassermann in the later years of the disease does not inevitably point to the prospect of grave lesions. A negative Wassermann after salvarsan, in the first year of the disease, does not mean that the patient is cured, or that lesions will not reappear, because the reaction may again become positive. The return of chancre, glands, eruption and positive Wassermann reaction, a few months after control of the disease by salvarsan in its first few weeks, does not prove reinfection.

**Standard of Cure.**—A person is not cured until all syphilitic spirochetes disappear from the body. This disinfection may be accomplished easiest during the early stage of the chancre. Hence, the importance of early diagnosis by dark field illumination, and the prompt and intensive use of salvarsan, followed by mercury. The standard of cure may be set as follows: One year without treatment, without any suspicious clinical signs, with several negative Wassermann reactions and no positive ones, and with a spinal fluid examination negative for syphilis.

**Calomel Ointment as a Prophylactic.**—Syphilis was regarded as an infection peculiar to man until Metchnikoff and Roux in 1903 transmitted the disease to the higher apes. Later it was found that monkeys and rabbits are susceptible. As a result of these experiments, certain important facts in reference to prophylaxis were discovered. Of all the

<sup>71</sup>Thirteen states, namely, Alabama, Indiana, Michigan, New Jersey, New York, North Dakota, Oregon, Pennsylvania, Utah, Vermont, Virginia, Washington and Wisconsin, have laws enforced relating to venereal disease in connection with marriage. The laws vary in wording, but the purport of all is to prevent the marriage of all infected with acute syphilis or gonorrhea.

<sup>72</sup>*Syphilis*, 1909, Cassell & Co., p. 553.

<sup>73</sup>*Jour. A. M. A.*, March 6, 1915, LXIV, 10, p. 804.

various germicidal substances tried, Metchnikoff and Roux found that mercurial inunctions are most successful in preventing the development of the chancre. Calomel ointment has proved itself best.

In a communication published in 1906, Metchnikoff and Roux<sup>74</sup> state that having tried 12 experiments on monkeys with uniformly satisfactory results, they next performed the experiment on a man. A student of medicine offered himself, and they assured themselves that he had never had syphilis, either acquired or hereditary. The man did not develop syphilis, although watched for more than three months. Seventeen days after the inoculation the two control monkeys that were not treated with the ointment developed primary lesions, while the monkey, treated after a twenty-hour interval, developed a chancre after thirty-nine days' incubation. It is interesting to note that the subject of this experiment was Maisonneuve,<sup>75</sup> who published this experiment on himself as part of his thesis for the doctorate.

Calomel ointment to be effective must contain 33 per cent. of calomel, should be incorporated in lanolin<sup>76</sup> as a base, and great care should be taken in its preparation to ensure thorough mixing. No doubt many failures in actual practice and even in some experiments may be attributed to ignorance or negligence on the part of the pharmacist in not following these directions.

With rare exceptions, those who have watched the use of the prophylactic among troops or other large bodies of men are enthusiastic in regard to the results obtained, but the figures and statements they present would hardly serve to convince the critical. In practice it cannot be expected that the use of the prophylactic will be invariably successful, but it seems reasonable to believe that if properly applied during the first hour after exposure it will prevent the great majority of syphilitic infections. The efficacy of the prophylactic diminishes rapidly as the time between its use and the exposure increases. In addition to this time factor, there will be variations in efficacy in practice, depending upon the care with which the calomel ointment is compounded and upon the intelligence and thoroughness with which the prophylactic is applied.

Colonel Edwin P. Wolfe,<sup>77</sup> who conducted work at Fort McKinley, P. I., found that only two cases of primary syphilis occurred among 19,465 men who were given prophylactic treatment, whereas 99 cases developed among men who did not receive the treatment. Acevodo<sup>78</sup> in 1908 reported 1435 prophylactic treatments in the Chilean Navy following exposures in ports all over the world: only 3 cases developed syphilis. See also page 81.

<sup>74</sup> *Bull. de l'Acad. de Med.*, 1906, LV, 554.

<sup>75</sup> *Thèse de Paris*, 1906, Steinheil.

<sup>76</sup> *Adeps lanæ hydrosus*, containing not more than 30 per cent. water.

<sup>78</sup> *Mal. Cutan. et Syphilitiques*, 1908, XIX, 868.

Excision, or destruction of the chancre with the actual cautery or with corrosive antiseptics does not influence the development of the disease.

Further measures for the prevention of syphilis are considered with Venereal Prophylaxis and Hygiene of Sex, pages 73 to 86.

**Summary.**—Syphilis affects about 8 per cent. of the total population, occurs at all ages and in all classes of society, is the cause of from 10 to 35 per cent. of all insanity, and is one of the causes of mentally and physically deficient children. It is the cause of locomotor ataxia, paresis, and the chief cause of apoplectic strokes in early life, and is responsible for a large proportion of diseases of the heart and blood vessels; is the cause of nearly half of abortion and miscarriages. Syphilis decreases the length of life about one-third; it also lowers the standard of health and paves the way for other diseases; it greatly decreases earning capacity; is the most serious cause of disruption of home and happiness, and causes untold suffering and misery. Withal, it is preventable and curable. The public health control of syphilis depends upon early diagnosis and facilities for prompt treatment.

### GONORRHEA

Gonorrhea is much more prevalent than syphilis, and common opinion regards it as a mild and not very shameful disease, that is, "no worse than an ordinary cold." As a matter of fact, gonorrhea is one of the serious infectious diseases, and the gonococcus occupies a position of high rank among the virulent pathogenic microorganisms. From an economic and public health standpoint, gonorrhea does not fall very far short of syphilis in importance.

The gonococcus occurs characteristically in the polymorphonuclear leukocytes as small, biscuit-shaped, Gram negative diplococci. The organism is aerobic and can be cultivated only on special media and then with difficulty. It is killed in a few minutes at 55° C. It soon dies when dried or when exposed to the air. It is very frail, outside the body, weak germicides being sufficient to kill the coccus. Cultures soon lose their virulence. Infantile types appear to be much less pathogenic than adult types.

The complications of gonorrhea are: periurethral abscess, prostatitis and epididymitis in the male; vaginitis, endocervicitis and inflammation of the glands of Bartholini in the female. Perhaps the most serious of all the sequelae of gonorrhea are those which result from the spread by direct continuity of tissues, such as inflammation of the uterus, often extending into the fallopian tubes to the ovary, and even the peritoneum. The gonococcus has been found in pure culture in cases of acute general peritonitis. Other inflammations caused by the spread of the infection

are cystitis, which sometimes extends upward through the ureters to the kidneys.

The gonococcus sometimes invades the blood and produces a general septicemia; death may occur from acute endocarditis. Gonorrheal arthritis is, in many respects, the most damaging, disabling, and serious of all the complications of gonorrhea. It may even follow ophthalmia neonatorum. It is more frequent in males than in females, but a gonorrheal arthritis of great intensity may occur in a newly married woman infected by an old gleet in her husband. The serious nature of gonorrheal complications in the eye will be considered separately under Ophthalmia Neonatorum. Gynecologists tell us that the greater part of their practice is made up of the consequences of gonorrhea.

Morrow<sup>79</sup> assures us that 80 per cent. of deaths from infections peculiar to women are due to gonorrhea. From 75 to 80 per cent. of all operations of the female genital tract are said to be due to gonorrheal infections alone.

Sterility is one of the serious consequences of gonorrhea. This may be caused in the male through epididymitis or orchitis, which is a very common complication, and in the female by salpingitis, which closes or obstructs the fallopian tubes. Gonorrhea is said to be the cause of about one-half of all cases of sterility.

Stricture of the urethra in the male is a frequent sequel.

Gonorrhea is usually transmitted by sexual congress; however, accidental or innocent infections are not infrequent, especially in children.

**Standards of Cure.**—It is difficult to determine when a case is cured. The following tentative rules are laid down by the U. S. Public Health Service:

Males: (1) Freedom from discharge. (2) Clear urine; no shreds. (3) The pus expressed from the urethra by prostatic massage must be negative for gonococci on four successive examinations at intervals of one week. (4) After dilation of the urethra by passage of a full-sized sound, the resulting inflammatory discharge must be negative for gonococci.

Females: (1) No urethral or vaginal discharge. (2) Two successive negative examinations for gonococci of secretions of the urethra, vagina, and the cervix, with an interval of 48 hours and repeated on 4 successive weeks.

The *diagnosis* of gonorrhea is usually made from stained smears of the secretions. Unless the preparation is well made, properly stained, and examined by a competent microscopist, the results may not be dependable. Positive results are indicated by the presence of Gram-negative diplococci in the leukocytes. Negative findings do not rule out the disease, especially in the female. The specificity of the complement

<sup>79</sup> *Boston Med. & Surg. Journ.*, 1911, CLXV, p. 520.

fixation test depends upon the technic and the operator: When positive, it indicates gonorrhea. A negative test does not exclude the disease. This test has not yet been standardized.

*Prevention.*—Inject, as soon after exposure as practicable, 2 per cent. protargol or 10 per cent. argyrol. See page 82

**Vulvovaginitis in Children.**—Vulvovaginitis (epidemic vaginitis) is common in children and is frequently due to the gonococcus. Outbreaks are common in schools, tenements, playgrounds, asylums, hospitals or wherever children congregate in considerable numbers and where the same lavatories, towels, nurses, etc., are provided in common. Paul Bendig<sup>80</sup> reports the following instance: Of 40 girls sent for convalescence to a brine bath, 15 showed signs of gonorrhea after the return. The infection came from an eight year old girl, who apparently had been suffering from gonorrhea for several years, and was spread through indiscriminate bathing in one bath tub and the use of the same bath towel.

Infants may contract the infection from the hands of the nurse. Syringes, bed pans, catheters, thermometers, towels, diapers, wash cloths, and bed linen may account for the transmission of the gonococcus in hospitals and asylums, although the rapidity with which the gonococcus dies when dried diminishes the danger somewhat from this source. Diapers should always be disinfected by boiling or steaming before they are again used, especially in institutions; this, not only on account of gonorrhea, but of infectious diarrheas. In the public bath, children who use the same towel, tub, soap, etc., run a great risk. Taussig<sup>81</sup> believes the seat of the water-closet favors the infection in little girls. These seats are usually too high and thus readily become smeared with the discharges from the vagina, and thus infect others. In schools and tenements the water-closets are often used by a stream of children one after another. Hence, such seats should be low and U-shaped.

The frequency of gonorrhea in children may be judged from the observations of Pollack, who reports 187 cases treated in the Women's Venereal Department of Johns Hopkins Hospital during the year 1919.<sup>82</sup> Pollack estimates that 800 to 1000 children are infected each year in Baltimore, and that the same proportion probably holds good for other cities. Seippel estimates that 500 cases occur annually in Chicago. One cause of the infection among children is the horrible superstition that a person infected with gonorrhea may get rid of it by infecting another—especially a virgin. Gonorrhea in children due to rape is rare.

When gonorrhea enters a children's hospital or an infant's home it is prone to become epidemic and is very difficult to eradicate. The

<sup>80</sup> *Münchener med. Wochenschr.*, 1909, p. 1846.

<sup>81</sup> *Amer. Journ. Med. Sciences*, CXLVIII, 4, Oct., 1914, p. 480.

<sup>82</sup> *Johns Hopkins Hospital Bull.*, May, 1909, p. 142.

story of the infection in the Babies' Hospital, New York, for eleven years, as told by Holt,<sup>83</sup> illustrates the singular obstinacy of the infection. In spite of the greatest care and precaution, there were, in 1903, 65 cases of vaginitis with 2 of ophthalmia and 12 of arthritis. In 1904 there were 52 cases of vaginitis, only 16 of which would have been recognized without the bacteriological examination. In all, in the eleven years, there were 273 cases of vaginitis; 6 with ophthalmia, and 26 with arthritis. Holt urges isolation and prolonged quarantine as the only measures to combat successfully the disease. It is impossible to control such epidemics without bacteriological diagnosis, aided by complement fixation tests.

Hess believes that the greatest obstacle to controlling the disease is the difficulty of recognizing latent cases. It is possible to convert the concealed carrier into an open case by means of provocative inoculations of gonococcus vaccines. The complement fixation test gives a very high percentage of positive results when gonococci are present, except in the very acute stage.

Epidemic vaginitis is intractable in children and tends to a spontaneous cure at puberty. Many cases continue for years despite careful treatment, and disappear spontaneously at puberty.

Complications and sequelae of vulvovaginitis in children are much less common than gonococcus complications and sequelae in the adult. Louise Pearce<sup>84</sup> has shown that the infant types of gonococci differ from the adult types when tested by agglutination and complement fixation. The infantile types are also much less virulent, and cause fewer complications.

The social and public health problems which this disease presents are very great, and our knowledge of the disease from the standpoint of diagnosis, quarantine, and treatment, is not sufficient to enable us to handle this question in a satisfactory manner. A diagnosis resting solely upon the morphological and staining characteristics of the organisms found in smears is not sufficient to brand a child with the diagnosis of gonorrhea. Vulvovaginitis in children is not a venereal disease. If the term gonorrheal or gonococcus vaginitis were dropped from the literature, and the term epidemic vaginitis substituted, it would be much easier to handle these cases from a public health standpoint.

For the prevention of vulvovaginitis in children, the good advice of the American Pediatric Society should be followed:<sup>85</sup>

(a) That cities be required to provide adequate hospital and dispensary facilities for the care and treatment of children having vaginitis.

<sup>83</sup> *N. Y. Med. Journ.*, March, 1905.

<sup>84</sup> *Journ. Exper. Med.*, XXI, 4, April, 1915, p. 289.

<sup>85</sup> *Arch. of Ped.*, XXXII, 1916, p. 361.

(b) That matrons be placed in charge of the girls' toilet rooms in public schools.

(c) That toilet seats embodying the principle of the U-shape be used in all schools and that the toilets be of proper height for different ages.

(d) That city and state laboratories be empowered and equipped to make bacteriological examinations for physicians when patients cannot afford to pay a private laboratory fee.

(e) That educational literature on the subject of vaginitis be prepared and distributed to mothers through the medium of physicians, hospitals, dispensaries, health centers, municipal and visiting nurses.

(f) That asylums for children and day nurseries be licensed and that the license be not granted unless: first, the institution has adequate facilities for the recognition of gonococcus vaginitis; and second, the institution excludes children having this disease if they cannot be properly isolated.

That the American Pediatric Society address a special letter to hospitals which care for children, containing the following recommendations:

(a) That separate wards be maintained for the treatment of children with vaginitis who are also suffering from other diseases.

(b) That microscopic examinations of smears be made before admission to the general wards of the hospital. In securing material for the smears extreme care should be taken to observe rigid aseptic precautions.

(c) That observation wards be provided.

(d) That individual syringes, bed pans, catheters, clinical thermometers, thermometer lubricant, wash basin, soap, powder, wash cloths and towels be provided.

(e) That single service diapers be used (at least for girls); or, that diapers be sterilized in an autoclave at 15 pounds pressure for five minutes.

(f) That nurses be required to make daily inspection of the vulva of each girl at the time of bathing and to report immediately the presence of the slightest suggestion of a vaginal discharge.

(g) That low toilets be provided and equipped with seats embodying the principle of the U-shape.

(h) That for routine purposes, the spray be used in place of tub baths for the bathing of young girls, and that older girls be sponged in beds.

(i) That nurses receive special instruction as to the nature of vaginitis, the ease with which it is transmitted, the methods of preventing its spread and the necessity for rigid aseptic surgical technic in its handling and treatment.

(j) That a dispensary with special facilities for the treatment of gonococcus vaginitis be provided.

(k) That nursing care and supervision be given in the home.

(l) That mothers be instructed as to the dangers of vaginitis, the manner in which it is transmitted, the best method of protecting other children, and the necessity of prolonged observation.

(m) That all cases of vaginitis under observation be voluntarily reported to the local health officer in states or cities where no legal requirements are in force.

**Summary.**—Gonorrhea is the most constantly prevalent of all serious infectious diseases, except measles; affects all ages and all classes of society; is responsible for from 6,000 to 10,000 cases of blindness in the United States; is the cause of 60 per cent. of blindness of the new born; is the cause of more than 10 per cent. of all blindness; is the cause of from 60 to 75 per cent. of surgical operations on the female generative organs; of 50 per cent. of sterility; of many chronic diseases of the joints, bladder and generative organs; greatly decreases earning capacity; is the underlying cause of untold suffering and misery; and affects practically all prostitutes, public and clandestine. Notwithstanding, gonorrhea is a preventable disease.

Further measures for the prevention of gonorrhea are considered with Venereal Prophylaxis and Hygiene of Sex, pages 73 to 86.

### CHANCROID

*Chancroid* is a specific, local, auto-inoculable, and contagious venereal ulcer, caused by the streptobacillus of Ducrey (1889). The ulcers are often multiple and confer no immunity. Chancroids are local ulcers and cause no sequelae or general systemic effects, such as follow chancres. Chancroids, or soft chancres, are peculiarly liable to mixed infections, and are apt to become phagedenic.

As many as 50 per cent. of soft chancres are mixed infections with the *Spirochæta pallida*. Every venereal lesion should be examined by dark-field illumination for spirochetes. This is of great importance from a public health standpoint as well as for individual prophylaxis.

A little soap and water at the time of exposure is almost an absolute preventive against chancroid. If the ulcer has developed it may be aborted by cauterization, provided the chancroid is not more than three days old. Even when seven days old the ulcers may often thus be cured, but when more than a week old, cauterization should not be employed, for, if it fails, it leaves the sore larger than ever. The method of cauterization advised by Keyes consists in washing the ulcers with peroxid of hydrogen, drying, applying pure carbolic acid, then pure nitric acid, washing again with peroxid of hydrogen, and dusting with

calomel. Spirochetecides should not be used locally until syphilis has been definitely excluded by dark field illumination.

Chaneroids are usually contracted in venery. The disease should not be regarded as a slight or negligible malady, for, on account of the mixed infections to which they are prone, serious consequences, and sometimes death, may result. The complications of the ulcers are various forms of phimosis, resulting from inflammation and swelling; destruction of the frenum; gangrene and phagedena; lymphangitis, with inguinal adenitis. The inguinal buboes are painful and frequently suppurate.

Chaneroid is usually given subordinate consideration because syphilis and gonorrhea are much more prevalent and much more serious.

## VENEREAL PROPHYLAXIS AND HYGIENE OF SEX

The same principles apply to the prevention of the venereal diseases as apply to the prevention of other communicable diseases. The fight against venereal diseases, however, is especially complicated and difficult because of the close association with prostitution, the problems of sex, morality, and alcoholism—in fact, the question pervades the woof and warp of society. There are three primitive appetites of man—hunger, thirst, and the sexual appetite. The first two persist throughout life; the last comes on at puberty, grows stronger during adolescence, and wanes with age. Any program for the control of the venereal diseases or the hygiene of sex must take into account the fact that we are dealing with a primal, impulsive, and natural passion which is the greatest force for social good, when used in accordance with the laws of nature, but may result in dire consequences when these laws are transgressed. The venereal diseases are among the most widespread and universal of all human ills, and enter more largely into the marring of domestic happiness than any other disease known to man. The difficulties of the situation should not deter the health officer and all those who labor for social uplift, for there is no more pressing problem in preventive medicine.

**Prevalence.**—The prevalence of the venereal diseases among the population at large can only be approximated. Definite figures, however, are at hand for selected groups. The reports from the armies of the various nations give the following figures:<sup>86</sup>

VENEREAL INFECTIONS PER THOUSAND MEN

	Years	Per Thousand
Germany .....	1905-6	19.8
France .....	1906	28.6
Austria .....	1907	54.2
Russia .....	1906	62.7
United States .....	1907	167.8
United Kingdom .....	1907	68.4

<sup>86</sup> White and Melville, *Lancet*, London, 1911, II, 1615.

Kober <sup>87</sup> gives a somewhat more recent and more detailed table.

DIFFERENTIATED INFECTION PER THOUSAND MEN

Year	Syphilis	Chancroid	Gonorrhea	Total
U. S. Army.....1909	30.45	30.77	135.77	196.99
U. S. Navy.....1909	26.49	28.23	105.11	159.83
Japanese Navy.....1907	.....	.....	.....	139.75
British Navy.....1908	37.46	17.87	67.16	122.49
British Army.....1908	35.1	28.23	40.7	75.8
Japanese Army.....1907	10.1	10.4	17.1	37.6
Prussian Army.....1907	4.4	2.1	12.2	18.7

Both these tables indicate that the English-speaking people are, in their navy and military organizations at least, greater sufferers from venereal infections than the other nations. The figures however are not strictly comparable, because of different methods used of recording these diseases. The venereal disease incidence, expressed as annual rates per 1,000 of mean strength for United States Continental (excluding Alaska) enlisted men, by years 1906 to 1917, follows:

1906 — 143.62	1912 — 115.74
1907 — 149.21	1913 — 85.83
1908 — 155.17	1914 — 89.84
1909 — 151.35	1915 — 83.60
1910 — 137.98	1916 — 91.23
1911 — 145.29	1917 — 113.82

Of the first 990,592 physical records received by the Surgeon General, U. S. Army, under the Selective Service Act, a total of 28,411 men had venereal disease—2.86 per cent. Of these, 23,049 had gonorrhea, 4,412 had syphilis, and 941 chancroid. Camp medical examiners found a higher percentage—5.4. These figures indicate the minimal amount of venereal disease coming from civilian life among the first million drafted. After enlistment, venereal cases expressed as annual rates per 1,000 of mean strength, averaged 15 during the year 1919. In slightly over a year and a half after the first drafted men were mobilized, 225,000 cases of venereal disease were reported to the Surgeon General, U. S. Army, among all troops in the United States. Approximately 200,000 of these were contracted in civilian life.<sup>88</sup>

In civil life accurate figures are not obtainable. Cunningham <sup>89</sup> says that 60 per cent. of men acquire venereal infection some time. Twenty per cent. of these are incurred before the 20th year, 50 per cent. before

<sup>87</sup> Kober, *Tr. Assn. Am. Phys.*, Phila., 1911, XXVI, 155.

<sup>88</sup> The venereal disease rate in American troops in France was about 45 cases per 1,000 men per annum. This rate was never before closely approached in the U. S. Army. The corresponding incidence rate in the United States averaged above 60.

<sup>89</sup> Cunningham, *Boston Med. and Surg. Jour.*, 1913, LXVIII, 77.

the 25th year, and 80 per cent. before the 30th year. Gerrish<sup>90</sup> estimates that 10 per cent. of the population of New York has syphilis. Fischer<sup>91</sup> guesses that 18 per cent. represents the syphilitic cases in the United States, and further, that there are 250,000 deaths each year due to venereal infections. Biggs<sup>92</sup> judges that there were about 200,000 cases of venereal diseases in the city of New York in 1912. Morrow<sup>93</sup> states that 75 per cent. of adult males acquire gonorrhea at some time, and that from 5 to 10 per cent. acquire syphilis; these figures are based, not alone on his own observations, but on the opinion of such men as Neisser and Fournier. Zinsser<sup>94</sup> estimates that 10 per cent. of the men registered for draft under the selective service act were actively infected. There were 24,234,021 men between 18 and 45 registered. It is conservatively estimated that of this number 2,600,000 were diseased, of whom 500,000 were syphilitic.

The pathologists of Melbourne, Australia,<sup>95</sup> found syphilitic lesions in 30 per cent. of 200 necropsies; furthermore, 5 per cent. of the population within a ten-mile radius from the Melbourne postoffice were positive to the Wassermann test. Banks<sup>96</sup> states that we have nearly two and one-half million cases of venereal diseases occurring yearly in the United States—about one person in every forty. These findings are ample to indicate the extent of the scourge. See also page 58.

**Attitude.**—Our attitude toward the venereal diseases is very inconsistent. There is a natural aversion toward these afflictions. The sanitarian should make no distinction between the venereal diseases and other epidemic diseases; he should regard the greatpox in the same light that he regards the smallpox. The principles for the control of syphilis and gonorrhea differ in no wise from those used to control smallpox, leprosy, tuberculosis, measles, diphtheria, etc. The health officer must not regard venereal disease as a punishment for sin—the victim or culprit needs help, even sympathy. *The immediate problem is the prevention of further spread of the infection.* A person afflicted with a venereal disease should be treated in the same humane spirit that actuates us in other diseases. Furthermore, the interests of the community require that the patient be accorded the best possible care and treatment. The usual attitude toward the venereal diseases may well startle us when we consider that in most of our large cities no hospital will take a case of syphilis or gonorrhea during the acute stages, when these diseases are especially communicable. Morrow holds that the notoriously inadequate provision made for the reception and treatment

<sup>96</sup> *Public Health Rep.*, Feb. 26, 1915, XXX, 9, p. 618.

of venereal patients is a disgrace to our civilization. Formerly lepers were segregated in vile lazarettos and cases of smallpox isolated in horrible pesthouses; now we have comfortable and congenial isolation wards or special sanatoria for these diseases. From the standpoint of prevention suitable hospital accommodations must be provided for venereal cases.

**Education.**—Education in sex hygiene and the venereal peril accomplishes a certain amount of good. A knowledge of the consequences will not control passion. Efforts to instill a wholesome fear of venereal diseases are futile. Even one attack of a venereal disease does not act as a deterrent to future immorality, and medical students who are presumably informed are no more moral than other members of the student body. The only education that will effect a reduction in immorality is the education that forms character and, as Huxley says, "Molds the desire to live in accordance with the laws of nature."

However, the old-style innocence must be regarded as present-day ignorance. Every boy and girl, before reaching the age of puberty, should have a knowledge of sex, and every man and woman before the marriageable age should be informed on the subject of reproduction and the dangers of venereal diseases. Superficial information is not true education. On the other hand, it is a mistake to dwell unduly upon the subject, for in many instances the imagination and passion of youth are inflamed by simply calling attention to the subject. One of the objects of education is to avoid the dangers of sex impurities, and all agree that this may often best be accomplished by keeping the mind clean, that is, away from the subject. The education must, therefore, be clear, pointed, brief, and direct. The object of education is not alone to help the individual to help himself, but to influence necessary legislation and concerted public action; also to lessen the influence of quacks. A simple knowledge of the facts is a sufficient deterrent for some; others may be influenced through fear of the consequences. Boys, as a rule, cannot be controlled through fear. The spirit of adventure is rife in healthy lads; they love to take a chance. Boys may be reached by an appeal to their better natures and by allusions to sister or mother. Normal boys are heedless of self, but are regardful of others: hence, a knowledge of the peril to future wife and offspring is the most impressive fact to keep boys straight.

Instruction in sex hygiene should emphasize the rewards of strength and virtue, rather than the penalties of weakness and vice. The only foundation for a healthy sex life is an individual and social morality, combined with a knowledge and full understanding of sexual realities. The teaching of sex from a biological standpoint alone is inadequate, for there is little basis for character forming or ethical instruction in the physiological analogies of animal and plant life. Instruction should be

positive rather than negative, constructive rather than destructive. The fear of disease or fear of anything else is not a sufficient motive for goodness. In contrast to the usual procedures, the emphasis should be placed on the beauty of goodness rather than on the ugliness of vice.

In general, it may be said that the best plan of education in matters sexual is to answer the questions of young children upon the subject of maternity frankly and truthfully, but to offer them no information on the subject. The growing child at the age of puberty should be offered a certain amount of information concerning unnatural habits and should study physiology, biology, especially botany, and the facts of fertilization. At about the age of sixteen or eighteen girls as well as boys should be instructed as to the venereal peril. Emphasis should be placed upon the future hazard to wife and offspring. The person to impart the information may be parent, doctor, minister, friend, or teacher—in any event, two qualifications are essential: (1) Knowledge of the facts; (2) an impressive personality. As a rule the school-teacher is not naturally endowed nor is the class-room the best place to attain the reverent attitude essential to teach lessons in sex hygiene.

Unless education in sex hygiene to the young is properly given, which is most difficult, it may do more harm than good. Some of it excites morbid curiosity, and there is a peculiar twist to human nature that drives many to do anything specifically charged not to do. The general reluctance of parents and teachers to discuss sex matters with the young is ascribed by many to prudery, but it is often a safe instinct to follow. The problem of sex should be approached in the spirit of personal reserve that we associate with the better sort of home life rather than in the spirit of eager curiosity and practical experimentation that we associate with the school. The ideal method of instruction in these matters is therefore individual. See also pages 439-441, 447, 448.

Admirable pamphlets are distributed by the United States Public Health Service, Washington, D. C., by the American Social Hygiene Association, 105 West 40th Street, New York City, and by some state and city boards of health.

Some of the facts all young men should know are: that the true purpose of the sex function is reproduction and not sensual pleasure; that the testicles have a twofold function, (a) reproduction and (b) to supply force and energy to other organs of the body; that occasional seminal emissions at night are evidences of normal physiological activity; that sexual intercourse is not essential to the preservation of virility; that chastity is compatible with health; and that the sex instinct in man may be controlled.

The primary function of the testicles is to build the boy into the man. Castration in early life, as in the case of eunuchs, results in

a loss of the internal secretion<sup>97</sup> of the testicles and a failure in development of the secondary sexual characters which distinguish the male. There are an alteration in physical conformation and in the voice, lack of beard, development of the mammae, etc.—in other words, an approach to the feminine type. Healthy sexuality stimulates the imagination, sentiment, the esthetic sense, and the higher creative functions. Excesses or any influence which weakens the sexual system impair the will power, influence self-respect, and diminish mental force. Experience shows that arduous physical and mental labor, even after maturity is attained, is best performed when the sex organs are not exercised; that is, sexual excess distinctly impairs muscular strength and mental efficiency. It is unwise to frighten boys by exaggerating the results of self-abuse, which is rather the effect and not the cause of idiocy, insanity, degeneracy, and other defects of the central nervous organization. Self-abuse is no worse in its effects than natural coitus, except for its influence upon character. Both are alike harmful when indulged in to excess.

Results through education will be slow, for the aggressive conscience of the world in these matters has awakened too recently to have achieved as yet a great deal. Good results are already apparent upon the youth of the growing generation.

**Notification.**—It is not possible to control any communicable disease, especially one that is pandemic, such as syphilis or gonorrhea, without a knowledge of the cases and deaths. It is perhaps even more important to collect morbidity and mortality statistics of the greatpox than it is of the smallpox. But the public registration of private disease at once defeats its own object. Compulsory methods are only partly successful, and little may be expected from voluntary registration. When we consider that in our country we have no means of knowing the amount and distribution of smallpox, except to a limited degree in the registration area, what can we expect from the registration of the closely guarded secrets of the underworld? The public registration of ophthalmia neonatorum is successful because this form of gonorrhea is so apparent and the consequences so immediate and serious.

Notification by serial number became effective in Massachusetts in February, 1918, and is meeting with increasing success. In the 11 months of 1918, 7,681 cases of gonorrhea and 3,284 cases of syphilis were reported to the State Department of Public Health; in 1919, 9,435 cases of gonorrhea and 4,127 cases of syphilis.

To be effective, compulsory notification must, in the judgment of the National Council for Combating Venereal Diseases, include as the first and most necessary measures: (1) The provision in every area of adequate facilities for prompt diagnosis and efficient treatment, free of

<sup>97</sup> Both the testes and ovaries produce hormones.

charge. (2) The prohibition of quack treatment. (3) Granting of privilege to any communication made in good faith by a medical man in order to prevent the spread of infection. False reporting by number does not, after all, give the information necessary to deal with the conditions. The Australian law requires notification by physicians and requires that the patient go to a qualified practitioner for treatment upon penalty of fine and imprisonment. Any system of notification without adequate facilities for treatment will fail of its purpose. The difficulties, however, need not deter us, and registration should be attempted even though the returns are incomplete. A start should be made, and, though the returns will be only partial at first, a gradual improvement may be expected. Every case known and properly cared for is a focus of infection neutralized.

**Continence.**—One of the important facts to teach boys is that continence is compatible with health. It is also the best preventive against venereal infection. The testicles are like the tear gland and the sweat glands, in that they do not atrophy with disuse. Benjamin Franklin taught, as many another man of influence believes to-day, that the exercise of the sexual functions is necessary for health. This is a mistake and has done much harm. The physiologic normal for frequency of nocturnal emissions in sexually abstinent males is commonly given as one to four per month.

The sex principle is universal in nature. It is the force behind the constructive and progressive processes of all life, from the color adaptations of birds and flowers to the highest leadership in men. Reproduction is only one of its many functions; and the man who assumes that the so-called physical desire that at times thrills him indicates a need of sexual intercourse is in danger of depleting and wasting from his life a chief source of physical and mental power.

The single standard for men and women must be insisted upon, and the parent or guardian is justified in demanding a clean bill of health of the young man who proposes marriage. The young man, in turn, is entitled to the same from his prospective father-in-law. One of the defects of our artificial civilization which leads to harm is the postponement of the marriage age.

To denounce youth as vicious when youth has merely followed the impulse of adolescence is futile, because youth will not believe this; other and juster reasons must be given, if youth is to listen and be controlled. Any young man, properly warned and properly informed will not be merely willing but anxious to learn from his doctor before marriage if he is fit to be a husband and a father.

Carnal lust may be cooled and quelled by hard work of the body, as well as attention to personal hygiene—hence, one of the great advantages of athletic sports for growing young men.

**Personal Hygiene.**—Idleness, stimulating food, overeating, impure thoughts, evil associates, and alcohol excite the passions and are the bed-fellows of the venereal diseases. Purity of mind and cleanliness of body are helpful prophylactics. Physical exercise and an out-of-door life divert the mind and help the body; it is a good safety valve for the excess animalism of youth. A full diet raises basal metabolism and stimulates sexual desire, whereas a low diet diminishes procreative interest and power.<sup>98</sup>

The public should be taught the necessity for thorough daily cleansing of the external genitals in both sexes, even in children. The large number of secreting glands and the decomposition of their secretions are liable to induce irritation and even minute lesions which open portals to infection of all kinds.

Circumcision is recommended as an aid to genital cleanliness; as a prophylactic against syphilis and chancroid, venereal warts, herpes, and epithelioma, balanitis and phimosis; and also as a deterrent to masturbation.

In order to prevent innocent infections it is necessary to educate the public to place chief dependence upon personal prophylaxis. The hazard of kissing, the common drinking cup, unsanitary barbers, and the unhygienic practice of mouthing pipes and other things must become better known.

**Alcohol.**—The strongest indictment against alcohol is that it excites the passions and at the same time diminishes the will power. The fact that alcohol blunts moral tone does much more harm than all the cirrhotic livers, hardened arteries, shrunken kidneys, inflamed stomachs, and other lesions believed to be caused by its excessive use. Alcohol is not a stimulant, but depresses the higher functions of the brain from the beginning. See Index for references to Alcohol.

**Prostitution.**—Any sanitary measures taken for the prevention of venereal diseases which do not include some method for treating the problem of prostitution are doomed in advance to failure, since they will ignore the main source and root of these diseases. Fournier<sup>99</sup> states that among the class of men seeking treatment in the hospitals of Paris, 72 per cent. of all syphilitic infections were derived from registered prostitutes, 25.1 per cent. were derived from clandestine prostitutes and general immorality, and only 2.7 per cent. of these infections from adulterous relations. The Chicago Vice Commission states that: "So long as there is lust in the hearts of men it will seek out some method of expression. Until the hearts of men are changed, we can hope for no absolute annihilation of the social evil." While waiting for the slow evolution that aims at bettering the moral fiber of mankind,

<sup>98</sup> Miles, *Jour. of Neur. and Mental Dis.*, Vol. 49, No. 3, March, 1919.

<sup>99</sup> *Les Chancres Extragenitaux*, Paris, 1897.

the following four ways of dealing with prostitution have been attempted: (1) *laissez-faire*, (2) suppression, (3) regulation, and (4) the systematic treatment of all infected. A policy of non-interference satisfies no one. Despite the difficulties and complexities of the situation, we must insist that prostitution be met with determined but humane action to lessen its extent and diminish its dangers. Prostitution must at least be made difficult and distant, for the extent of the patronage is in direct ratio to its accessibility. The elimination of prostitution is beyond the dream of even the theoretical reformer. Any program must take into account the facts that a great majority of prostitutes are feeble-minded.

Suppression does not suppress. Virtue cannot be secured by legislation. Repressive measures drive the traffic into obscurity and reduce it materially. Vice is not flaunted in public, but is driven into corners where the vicious will find it, but where it will not entice the innocent and unwary. Between the flagrant evil of segregation and the imperfections of suppression, the choice is with the latter.

Regulation of prostitution by means of medical inspection and license has proven a failure wherever tried. Regulation implies the absence of any expectation of male self-restraint; it is society's tacit assent to laxity. Regulation fails because it makes vice easy, gives a false sense of security, and does not reach clandestine prostitution. The systematic treatment of all infected persons, especially of prostitutes, would go far towards diminishing the prevalence of venereal disease. To accomplish this, we must have adequate facilities for treatment. See page 85.

**Segregation.**—Theoretically, every case of syphilis or gonorrhea should be isolated until the danger of infection is passed. Practically, however, segregation is impracticable except with a limited number of cases. With better and more attractive hospital facilities and free beds a certain amount of segregation may be accomplished voluntarily and humanely. An alert health officer can trace the source of infection in certain cases and induce the women responsible to take the salvarsan treatment in the case of syphilis, or to submit to hospital care in the case of gonorrhea or chancroid.

Sanitary isolation through self restraint and care necessary to prevent the infection of innocent persons must be taught and impressed upon all infected individuals.

**Medical Prophylaxis.**—In accordance with the researches of Metchnikoff and Roux a reasonably efficient prophylaxis against syphilis is now possible.

Calomel ointment (33½ per cent.) applied within an hour of intercourse is generally effective in preventing syphilitic infection. There are several more or less efficient irrigations or ointments destructive to the gonococcus if used soon enough—the silver salts being the best

(2 per cent. protargol or 10 per cent. argyrol). Prophylaxis is therefore possible, but it takes a great deal of care and vigilance, and the double method must be promptly and skillfully applied in order to be effective. It has been used with success in armies and navies, but in civil life, where strict routine and control of men are impossible, it is impracticable except in individual instances; even then it requires *time, intelligence, and sobriety*. For this reason, it has been found inadvisable to furnish soldiers and sailors with prophylactic packages.<sup>100</sup> Better results are obtained by shortening leaves of absence and applying the prophylactic by competent attendants. To be effective it should be applied within six hours of beginning of exposure; the best results are obtained when used within one hour.

*Method of Using Prophylactic.*—Before intercourse use a liberal amount of vaselin or other lubricant. This aids in preventing abrasions and forms a coating through which infectious organisms penetrate with difficulty. As soon as possible after intercourse:

1. Wash the genitalia thoroughly with soap and water, using plenty of soap. Soap solution is a spirocheticide, and there is good evidence that chancroid infection may also thus be avoided.

2. When the prophylaxis is performed under medical instruction or by a man of sufficient intelligence this may be followed by a wash of 1-1000 mercuric chlorid. The efficacy of this solution is undoubted, but it should not be used by ignorant persons, nor should bichlorid of mercury tablets be issued as a routine.

3. Dry, and apply about 1 dram of 33 per cent. calomel ointment in lanolin. Anhydrous lanolin<sup>101</sup> should not be used, and the ointment should be most thoroughly mixed. This should be well rubbed in for at least ten minutes, paying particular attention to the glans, corona and prepuce, but neglecting no part of the penis and the anterior portion of the scrotum. This should be rubbed in for at least ten minutes, and should not be removed but should be allowed to remain for 12 hours, meanwhile protecting the clothes by the application of an impervious paper napkin. This favors absorption and ensures prolonged action of the mercury on any organisms that may remain.

4. For the prevention of gonorrhea, a solution of argyrol 10 per cent. or protargol 2 per cent. should be injected into the urethra.

In the United States Navy the following method is employed: The entire penis is scrubbed with liquid soap and water for several minutes and then washed well with a solution of mercuric bichlorid, 1 to 2,000 in strength. If there are any abrasions present, they are sprayed with hydrogen peroxid from a hand atomizer. The man is then placed in

<sup>100</sup> Package K of the Army; and Sanitube of the Navy containing 33½ per cent. calomel and 2 per cent. tricesol.

<sup>101</sup> Adeps lanæ hydrosus, see page 66.

a sitting position, well forward in a chair in front of a convenient receptacle, and given two injections of a 10 per cent. solution of argyrol. He is required to retain each injection in the urethra for five minutes. After taking the injections, the entire penis is thoroughly anointed with a 33 per cent. calomel ointment. He is told not to urinate for at least two hours, and to allow the ointment to remain on the penis for some hours. A temporary dressing is placed on the parts to protect his clothes.

Medical prophylaxis has been in general use in the United States Army and Navy since about 1908, and since 1912 the use of prophylactics has been compulsory in the army. Many officers have published their opinions, for the most part favorable, and a few have furnished some statistics.

The best figures on this subject are given by Riggs,<sup>102</sup> who records 5,103 prophylactic treatments with only 81 infections, as shown by the following table:

Hours Subsequent to Exposure	Number of Treatments	Number of Infections (Syphilis, Gonorrhea, Chancroid)	Per cent. of Infections
1	1,180	1	0.08
2	1,172	7	0.59
3	521	4	0.77
4	330	2	0.61
5	199	3	1.57
6	321	5	1.58
7	277	6	2.27
8	390	16	4.22
9	283	10	3.62
10	214	11	5.14
More than 10	216	16	7.40
	Total.. 5,103	81	1.58

There were 1,180 treatments during the first hour which were followed by a single infection. This infection was carefully investigated and there is considerable doubt as to whether it was genuine or not. The disease was diagnosed as chancroid, and was cured in two days. These figures emphasize the importance of time—the efficiency of the prophylactic diminishes as the time increases. Riggs states that out of 3,556 prophylactic treatments there were only 67 infections, and of these only 8 were cases of syphilis.

Ledbetter<sup>103</sup> reports that at Cavite, before medical prophylaxis was instituted, the percentage of venereal diseases of all classes among the men averaged from 25 to 30 per cent. annually, and at times even higher. The percentage of gonorrhea was reduced to 8 per cent. annually, and this percentage included about 30 patients who did not re-

<sup>102</sup> *Social Hygiene*, 1917, III, 299.

<sup>103</sup> Ledbetter, Robert E., "Venereal Prophylaxis in the U. S. Navy." *Jour. A. M. A.*, April 15, 1911, Vol. LVI, No. 15, p. 1098.

port for treatment. Chancroid was reduced from 5 to 2 per cent., which included 2 patients not reporting for treatment. Syphilis has been reduced from about 20 cases annually to one case for the entire year 1910, and this patient did not report for prophylactic treatment. The results speak for themselves and show the efficiency of the prophylactic measures if properly and thoroughly carried out.

Holcomb and Cather<sup>104</sup> report the following as a result of treatment used by them in 3,268 persons in the U. S. Navy between May 1, 1910, and August 31, 1911. Treatment taken within eight hours after exposure in 1,385 cases shows 19 infections, or but 1.37 per cent. In the interval of from eight to twelve hours after exposure in 741 cases shows 25 infections, or 3.31 per cent. Between twelve and twenty-four hours in 920 cases shows 46 infections, or 5 per cent. Of the 56 cases of gonorrhea occurring in the first twenty-four-hour interval, 26 were recurrent cases; the remaining 30 were primary infections.

Riggs states that the normal expectancy for venereal disease resulting from illicit sexual intercourse not followed by prophylaxis is about 1 in 20 or 1 in 30. The expectancy for venereal disease when prophylaxis is used depends almost entirely upon the factor of time. The absence of the time factor in a set of prophylactic statistics invalidates any conclusion that may be drawn concerning probable efficiency of prophylaxis. In actual practise the number of infections appears to be reduced by nearly one-half. The questionnaire method of investigation, in which the identity of the individual is concealed, has proved unreliable and the results obtained cannot be accepted with any confidence as to their accuracy. Furthermore, many of the reported results are difficult to analyze on account of lack of accurate data, and especially lack of control figures.<sup>105</sup>

The use of salvarsan early in syphilis will prevent the further spread of the infection.

*Mechanical Methods.*—The condom was introduced late in the 17th or early in the 18th century in England. It was described by Turner in 1717, who attributed its invention to a Dr. Condom, from whom the device was named. Le Pileur, who has made a study of this literature, questions the existence of Dr. Condom, and thinks it more probable that the name is derived from the Latin verb *condere*, meaning to hide or to protect. Most authorities agree that the use of a condom is an almost certain protection against venereal infection, being even more reliable than prophylactic ointments. In regard to the protection afforded, we may conclude that the condom if properly tested and made of good rubber will afford practically complete protection to anyone who can

<sup>104</sup> Holcomb, R. C., and Cather, D. C., U. S. N., "Study of 3,268 Venereal Prophylactic Treatments," *Jour. A. M. A.*, Vol. LVIII, No. 5, February 3, 1912, p. 368.

<sup>105</sup> U. S. Naval Med. Bull., 1921, Vol. XV, No. 1.

obtain and will use it, and it may therefore be recommended to those individuals who persist in immorality in spite of advice to the contrary.

**Specific Treatment.**—From the standpoint of preventing syphilis, the treatment of the infected is perhaps the most efficacious single method that can be applied. It is obvious that if all infected individuals are rendered incapable of transmitting their infection, the disease will disappear. Notification, early recognition, and prompt treatment, therefore, become our most important prophylactic measures against syphilis.

Salvarsan (arsphenamine and related arsenical compounds) promptly kills the spirochetes in the chancre, mucous patches and other exposed lesions, and thereby destroys the focus of infection. Salvarsan promptly used is a specific and a preventive, even though some of the parasites hidden in the cells of the inner organs escape destruction. Unfortunately, salvarsan has always been a drug of the proprietary class, made in an atmosphere of mystery, under a patent giving an imperfect account of its preparation, produced at small cost and sold at a very high price. Recent efforts in this country to make and distribute this chemical free of charge in the same way that antitoxins and vaccine virus are distributed by boards of health is a commendable public health measure.

The danger of syphilis to the community or individual is increased in proportion to the inadequacy of the treatment received by those suffering with the disease. The possibility of controlling the amount of syphilis acquired, whether by prostitution or general immorality, by means of enforced systematic treatment, has not yet been given the serious consideration that the subject merits. When proper facilities are afforded the poor for the treatment of this class of diseases, one of the main props of the quack will have been removed. The Massachusetts State Department of Public Health has made and distributed arsphenamine free of charge since December, 1917.

**Hospitals and Clinics.**—Pontoppidan, on the basis of his large experience with the Danish system, estimates that 1 bed to 2,000 of the population is insufficient to care for sexual diseases. Stokes,<sup>106</sup> says that in 1914 it was estimated that the city of London, with 7,000,000 inhabitants, had only 163 beds available for the treatment of venereal disease, and the same condition obtained throughout Great Britain. Of 30 general hospitals in New York City, a recent investigation showed that only 10 received recognized cases of syphilis; 13 of 30 will not receive medical cases with complications of syphilis or gonorrhea. Chicago has 200 beds in the Cook County Hospital for 2,000,000 people. All the contemporary comment clearly indicates that the attitude of the general hospital toward syphilis and other venereal diseases is slowly changing. Special hospitals for the treatment of venereal diseases will not serve the

<sup>106</sup> *Jour. A. M. A.*, 1916, LXVII, 1960.

purpose, for while a patient might go to a general hospital for the treatment of these conditions, very few would seek assistance in a hospital openly devoted to the treatment of venereal diseases because of the stigma necessarily attached. Every general hospital should have wards assigned for the treatment of syphilis and gonorrhea. Beds are necessary in order that salvarsan or similar drugs may be administered under proper safeguards. No patient would occupy a bed long, since salvarsan usually causes a prompt disappearance of external lesions. It will be generally admitted that present facilities are sadly deficient, and that the extension of those facilities should be among the first steps to be taken to control this disease.

**Summary.**—Finally, in considering venereal prophylaxis, it should be remembered that these diseases are of great antiquity and seem likely to continue indefinitely; that they already affect a large number of the population, and are spreading; that the existing means for the treatment of them among the poor is insufficient; that the common mode of propagation is irregular and illicit intercourse; that prostitution arose in response to the strongest instincts and passions in the human breast; and that prostitutes themselves need protection and have claims on the humanity of the law. Furthermore, Lecky thinks that “The prostitute is ultimately the efficient guardian of virtue.”

To diminish the amount of venereal infection requires education and publicity, notification, laboratory facilities for diagnosis, dispensary and hospital facilities, public health nurses and social service, and good laws actively administered. Medical schools should give more time to the diagnosis and handling of early syphilis, since at this time the best results in treatment and prevention can be offered. A stricter supervision of barber shops, restaurants, hotels, soda water fountains, infant asylums and schools should be maintained; prostitution should be made difficult and distant and early treatment of all cases instituted. Medical prophylaxis should be better understood and the importance of personal hygiene impressed. Insistence should be stressed upon continence and efforts made to improve the moral and physical fiber of mankind.

**PREVENTABLE BLINDNESS**

Preventable blindness is considered in this place because the largest single factor causing needless loss of eyesight is gonorrhea. Among the infectious eye troubles the most destructive is ophthalmia neonatorum.

There were 64,000 registered blind persons in the United States, according to the census of 1910.<sup>107</sup> Ten per cent. (between six and seven thousand) are blind as the result of ophthalmia neonatorum. From 25 to 30 per cent. of all the blind children in all the blind schools of this country owe their infliction to gonorrhea. It has been estimated that probably one-half of the blindness in the world is preventable.

Emphasis upon the great harm done by ophthalmia neonatorum should not blind us to the fact that there are other causes of blindness and eye deterioration which are preventable; thus we have to consider the later pus infections, also syphilis, tuberculosis, smallpox, trachoma, sympathetic inflammations, industrial accidents, accidents at play, progressive near-sightedness caused by violation of ocular hygiene, and a variety of inflammatory conditions. Functional disturbances of vision (toxic amblyopia) followed in severe cases by atrophy of the optic nerve and permanent blindness may be brought about by poisoning with lead, wood alcohol, tobacco, and other poisons. This form of dimness of vision, or even loss of sight, occurs rather frequently, and in most instances is preventable.

One of the common causes of impaired sight is *phlyctenular keratitis* which leaves scars on the cornea. This condition is often associated with tubercular glands of the neck and is probably a form of bovine tuberculosis, hence preventable.

**OPHTHALMIA NEONATORUM**

Ophthalmia neonatorum or inflammation of the eyes of the newborn includes all the inflammatory conditions of the conjunctiva that occur shortly after birth—usually before the end of the first month. The conjunctivae of the newborn are peculiarly liable to infections. The gonococcus is usually the cause of severe conjunctivitis occurring in a baby a few days old. The gonococcus causes about 60 per cent. of all cases, mild and severe.

<sup>107</sup> These figures we now believe are altogether too low. Green states that in Massachusetts only about 53 per cent. of the actual cases had been recorded, and estimates the total blindness in the United States to be not less than 118,999. The figures vary greatly, because there is no accepted rule as to what constitutes blindness. A watchmaker would be practically blind with vision ample for a mason.

Ophthalmia neonatorum is not always gonorrheal, but may be produced by other virulent microorganisms or by irritating substances. The microorganisms other than the gonococcus that sometimes cause conjunctivitis during the early days of life: pneumococci, streptococci, meningococci, the Koch-Week's bacillus, the diphtheria bacillus, and even staphylococci. These are relatively so rare or benign that we may disregard their etiological significance for our present purpose. The diagnosis of gonorrheal ophthalmia may readily be made by simply examining a stained smear of the secretion for Gram-negative, biscuit-shaped diplococci, although in rare cases infection with the micrococcus catarrhalis may cause confusion.

The infection commonly occurs during the passage of the child through the genital tract of the mother and usually just before delivery. It is caused by the entrance of the vaginal secretion containing gonococci into the conjunctival sac. It may also occur after delivery by infected hands, towels, sponges, or other objects.

The disease varies in severity; sometimes it is very mild, with slow onset and spontaneous recovery. Usually, however, it is severe and serious. The inflammation may extend from the conjunctiva to the cornea leading to corneal ulcers and partial or complete loss of vision. In a typical case both the ocular and palpebral conjunctivae are red and very much swollen; the eyelids and surrounding tissues are infiltrated and there is a thick, creamy, abundant secretion.

There are many grades of mild inflammatory conditions, which must not be mistaken for gonorrhea. At birth the eyelids are almost always glued together with a normal sticky secretion. It is common, too, for the lids to remain red and sticky for a day or so. The diagnosis may be made in a few minutes by a microscopic examination.

**Prevalence.**—Kerr calls attention to the fact that there are no complete statistics showing the prevalence of ophthalmia neonatorum, and only an approximate idea can be had of the number of cases by studying the admissions to schools for the blind. A committee of the British Medical Association found that more than one-third of those in blind schools of Great Britain owed their affliction to this disease.<sup>108</sup>

In the United States and Canada, in 1907, out of 224 admissions to 10 schools for the blind, 59, or 24.38 per cent., were blind as a result of ophthalmia neonatorum;<sup>109</sup> and out of 351 admissions to certain schools in the United States and Canada in 1910, 84, or 23.9 per cent., were blind from this cause.<sup>110</sup>

As a result of studies made of ophthalmia neonatorum in 10 manufacturing cities of Massachusetts, Greene has presented figures which

<sup>108</sup> *British Medical Journal*, May 8, 1909.

<sup>109</sup> *Jour. A. M. A.*, May 23, 1909, p. 1745.

<sup>110</sup> *Jour. A. M. A.*, July 1, 1911, p. 72.

show that the minimum morbidity rate for this disease was 6.4 per 1,000 births. A more complete census made by him from the practice of 173 physicians in 9 cities revealed an average morbidity rate of 10.8 per 1,000 births.<sup>111</sup>

It is estimated that the total annual loss from gonorrheal ophthalmia in the United States is seven million dollars, and that more than one million dollars annually is spent in partially caring for its victims. A blind child costs the community an excess of about \$4,500 for its schooling.

**Prevention.—CREDÉ'S METHOD.**—Credé in 1881 introduced an efficient method of preventing ophthalmia neonatorum at the Lying-in Hospital at Leipzig, thereby connecting forever his name with the prevention of the disease and the subsequent saving of the sight of many persons. Credé's original method consisted simply in placing one or two drops of a 2 per cent. solution of silver nitrate in each conjunctival sac, as soon as practicable after the birth of the head.

In order to prevent gonococcic as well as other infections of babies' eyes, the following procedure is recommended: During pregnancy women should be instructed to practice daily external cleansing with soap and water and a clean wash-cloth. In case of any irritating discharge or even profuse white discharge, a physician should at once be consulted.

Immediately after labor the eyelids should be carefully cleaned with sterile absorbent cotton or gauze and a saturated solution of boric acid. A separate pledget should be used for each eye and the lids washed from the nose outward until quite free of all mucus, blood, or meconium without opening the lids. Next the lids should be separated and one or two drops of a 1 per cent. silver nitrate solution should be dropped into each eye, between the outer ends of the lids. The lids should be separated and elevated away from the eyeball so that a lake of silver nitrate solution may lie for one-half minute or longer between them, coming in contact with every portion of the conjunctival sac. *One application only* of the silver nitrate should be made, and ordinarily no further attention need be given to the eyes for several hours. Each time the child is bathed the eyes should first be wiped and cleaned with pledgets of sterile absorbent cotton wet with a saturated solution of boracic acid.

Credé used a 2 per cent. solution of silver nitrate, but, as this is sometimes irritating, a 1 per cent. solution is now commonly employed, and seems to afford equally efficient protection. The silver nitrate solution should be instilled into each conjunctival sac but once. Repeated applications may cause serious inflammations. In fact, a single treatment sometimes causes a conjunctivitis, known as "silver catarrh."

<sup>111</sup> *Monograph Series of the American Association for Conservation of Vision*, Vol. I, No. 1.

Other prophylactic substances have been proposed. The best substitutes are the newer silver compounds, as argyrol, which is a colloidal silver (25 per cent.), or protargol (3 per cent.). The following have also been recommended: Bichlorid of mercury, 1-2,000 or 1-5,000, silver acetate, 0.23 per cent., recommended by Zweifel, who used it in 5,222 cases. Schmidt and Rimpler recommend *aqua chlorini*. Carbolic acid (1 per cent.) or other antiseptics have also been tried. No substance, however, is known to be as reliable as silver nitrate, which should be used in all cases where there is any reason for believing that the mother is infected with the gonococcus.

There is no specific treatment for this disease. While silver nitrate and the various silver preparations are undoubtedly effective as prophylactics, when once the organisms have penetrated the tissues these agents can no longer reach them in effective concentration and hence are useless in treatment. They are, however, still generally used for this purpose. The disease is practically self limited, but the frequency of corneal complications can be greatly reduced by frequent irrigations with non-irritating solutions, such as boric acid or normal saline solution. Great care should be taken not to abrade the cornea.

As a general rule, it is advisable to use a prophylactic as a matter of routine in hospital and private practice. To use Credé's method upon every case necessitates the unpleasant suspicion that every woman is a possible source of gonococcus infection. If statements of the father about his previous life can be relied upon, an eye prophylactic may be omitted. In his private work Williams uses a boric acid solution except where there is special reason for believing that the mother has gonorrhea. The responsibility for risking the baby's eyes rests upon the medical attendant. There can only be one safe rule in case of doubt. It should be remembered that gonococcic infections of the conjunctiva occur in about one to every two hundred births (Edgar).

The good results of Credé's method are sufficiently convincing to justify criminal proceedings upon those who fail to apply this simple prophylactic. Credé reduced ophthalmia neonatorum in the Leipzig Lying-in Hospital from 10.8 per cent. to 0.1 per cent. Haab reduced the frequency of ophthalmia neonatorum in hospital practice from 9 to 1 per cent., while the statistics of many hospitals show only a very small fraction of 1 per cent. At the Sloane Maternity Hospital in New York, there were 4,660 births during a period of 6 years, in which Credé's method was carried out without a single case of ophthalmia. Stephenson's results are typical. In 2,265 births, ophthalmia neonatorum developed in 10 per cent. of the cases preceding the use of Credé's method. In 1,160 births after this method only 0.17 developed any trouble.

The technic of applying the nitrate of silver is very important, for, in the opinion of Edgar, when ophthalmia neonatorum develops after

the use of nitrate of silver, it is due either to a secondary infection or to the fact that the solution does not really bathe the mucous membranes, but remains upon the lashes. The lids must be everted and the silver solution placed in the conjunctival sac either from a glass rod or a pipette. Care must be taken not to touch or injure the delicate membrane.

Credé's method does not strike at the root of the evil. It would, of course, be much better to eradicate gonorrhea from men and women than to be compelled to drop silver nitrate into babies' eyes. Wrapped up with the question of ophthalmia neonatorum is the question of midwives, for to prevent blindness we must have intelligent and conscientious obstetrical attendants, especially for the poor and ignorant classes. Midwifery practice needs regulation, supervision, and elevation. Education is one of the bulwarks of prevention in this as well as other preventable infections.

**Legislation.**—Ophthalmia neonatorum is an instance in which "the protection of the citizen from the assaults of ignorance, indifference, or neglect, when they threaten his well-being and even his economic efficiency, is a duty which the state cannot evade and which he has a right to exact."

Laws for the prevention of the blindness of newborn infants are making progress slowly. Many states have now made prophylaxis compulsory. In some states the nurse, midwife, or parent is required to report the disease, in other states the attending physician.

Maine was the first state to take legal steps in 1891 to control ophthalmia neonatorum. In 1892 New York followed, with an amendment to the law relative to midwives and nurses. Subsequently most of the other states took legislative action.<sup>112</sup> The provisions of the several

<sup>112</sup>Kerr, J. W., "Ophthalmia Neonatorum: An Analysis of the Laws and Regulations Relating Thereto in Force in the United States," *Public Health Bull.* No. 49, U. S. P. H. & M. H. S., October, 1911.

The Massachusetts law reads as follows:

*Section 49.* . . . Should one or both eyes of an infant become inflamed, swollen and red, and show an unnatural discharge at any time within two weeks after its birth, it shall be the duty of the nurse, relative, or other attendant having charge of such an infant to report in writing within six hours thereafter, to the board of health of a city or town in which the parents of the infant reside, the fact that such inflammation, swelling, and redness of the eyes and unnatural discharge exist. On receipt of such report, or of notice of the same symptoms given by a physician as provided by the following section, the board of health shall take such immediate action as it may deem necessary in order that blindness may be prevented. WHOEVER VIOLATES THE PROVISIONS OF THIS SECTION SHALL BE PUNISHED BY A FINE OF NOT MORE THAN ONE HUNDRED DOLLARS.

*Section 50.* . . . If a physician knows that . . . if one or both eyes of an infant whom or whose mother he is called to visit become inflamed, swollen, and red, and show an unnatural discharge within two weeks after birth of such infant, he shall immediately give notice thereof in writing over his own signature to the selectmen or board of health of the town; AND IF HE REFUSES OR NEGLECTS TO GIVE SUCH NOTICE, HE SHALL FORFEIT NOT LESS THAN FIFTY NOR MORE THAN TWO HUNDRED DOLLARS FOR EACH OFFENCE. (Revised Laws, Chapter 75.)

laws are quite varied. In all of them, however, the object is to insure early treatment, and to this end compulsory notification is generally required. The health authorities of many states furnish prophylactic outfits to physicians. The outfit ordinarily consists of a small vial, protected from the light, containing a 1 per cent. solution of nitrate of silver, a sterilized dropper and bulb, and a circular of instructions.

In 3 years following the enforcement of the law of 1911, Massachusetts reduced the number of cases of blindness from this cause 50 per cent.; and in 1919 and 1920 no new cases of blindness from gonorrheal ophthalmia occurred. Good results are also evident in New York and wherever intelligent measures are vigorously carried out.

In order to make material progress against ophthalmia neonatorum, as well as against infant mortality, it is essential that laws require prompt report of all births; it is the duty of the health authorities to see to it that such laws are effectively carried out.

## TRACHOMA

**Trachoma** is a menace to the integrity of sight. It is a specific, communicable, destructive inflammation of the conjunctiva, characterized by the formation of the so-called trachoma granulations, which may be either papillary or follicular; the ultimate formation of scar tissue; marked chronicity and intractability to all forms of local treatment. The disease has been transmitted experimentally in human beings and possibly also in apes, but neither the degree nor the nature of its contagiousness is understood. The virus of trachoma is probably frail. Important factors in communicability are poor hygienic surroundings and lowered resistance from any cause, which accounts for the slow and uncertain manner in which the disease spreads in families. The disease may occasionally be confined to one eye.

The filtrability of the virus of trachoma remains undetermined. Experimental evidence permits no more than the suspicion that the virus may be filtrable under some circumstances. In 1907 Prowaczek<sup>113</sup> described the so-called inclusion or trachoma bodies. The nature of these bodies and their possible etiologic relation to trachoma still remain undetermined. Noguchi and Cohen<sup>114</sup> have reported the successful cultivation of these inclusion bodies, but since the cultivated bodies proved non-pathogenic the question still remains an open one.

Trachoma flourishes best where sanitary conditions are worst; it occurs chiefly among the overcrowded, underfed and overworked. The

<sup>113</sup> Halberstädter and Prowaczek. *Deut. med. Wochenschr.*, 1907, XXXIII, 1285, *Arb. u. d. k. Gesundheitsamte*, 1907, XXVI, 44.

<sup>114</sup> "Experiments on Cultivation of So-Called Trachoma Bodies," *Jour. Exp. Med.*, 1913, XVIII, No. 5.

diagnosis rests upon the history and the appearance of the lesions, especially scar tissue, papillary granulations, trachoma follicles and pannus of the cornea.

Trachoma presents varying clinical aspects, and as there is no criterion of the disease, errors in diagnosis are frequent. It should be differentiated from other inflammatory conditions of the conjunctiva, especially from *follicular conjunctivitis*, which is benign; from *vernal catarrh*, which is accompanied by a peculiar pavement-like appearance and pronounced subjective symptoms during the first warm days of spring; from *Parinaud's conjunctivitis*, which is an acute febrile disease, with glandular enlargements, and conjunctivitis usually limited to one eye.

Impairment of vision can be prevented and often greatly improved by surgery—grattage. Adults who for years have been burdens to themselves and often charges on the community, and children who have been compelled to remain out of school have been “cured” by surgical methods. Free trachoma hospitals have been established in Kentucky, Virginia, West Virginia, Tennessee, and North Dakota.<sup>115</sup>

A case cannot be said to be cured until all the conjunctiva of the upper lids has become replaced by smooth, white, avascular, fibrous scar tissue, and the lower lids are free from any evidence of disease. The control of trachoma consists in eliminating the foci of the disease, improving personal hygiene, and community sanitation. The disease is slow and insidious in its development; acute or fulminating cases are rare. Impairment of sight is due to involvement of the cornea, especially to scars resulting from recurring corneal ulcers.

The infection is rubbed into the eye by roller towels, handkerchiefs, fingers, and other ways. When once established, the disease is chronic, and permanent cures are doubtful.

Trachoma is much more prevalent in the United States than is ordinarily supposed. It is not an exotic disease, but a public health problem of some magnitude in many states. The public eye clinics of Chicago are filled with patients showing the resulting deformities. Wilder located a center in southern Illinois, and it has also been found in the mountains of Kentucky and Tennessee, while in Oklahoma this disease has become a public menace. It is more or less prevalent in the poorer sections of all the larger centers.

Trachoma is of such a serious nature that all immigrants arriving at our shores have their eyelids everted and conjunctivae examined for evidence of this infection. An alien immigrant arriving with trachoma is deported, and the steamship is liable to a fine of one hundred dollars for bringing every case of trachoma where it can be shown that the disease might have been recognized at the port of departure.

<sup>115</sup> J. A. M. A., October 23, 1920, p. 1109.

### TOXIC AMBLYOPIA

*Toxic amblyopia* may be caused by wood alcohol, tobacco, lead, quinin, salicylic acid, male fern, santonin, iodoform, atoxyl (arsenilic acid and derivatives), and also digitalis.

**Wood alcohol.** Columbian spirits, methyl alcohol ( $\text{CH}_3\text{OH}$ ), causes blindness through atrophy of the optic nerves. As small a quantity as a teaspoonful has caused loss of vision. Blindness may even be caused by inhaling the vapor. Quantities as small as 0.2 per cent. in the inspired air may accumulate in the body and cause toxic effects. Wood alcohol is used as an adulterant, especially in liquors and lotions, and also in industry as a solvent. It should be prohibited in any form of material used for internal or external use on the human body. Ample ventilation should be provided in all works where wood alcohol is made or used, as in brewery vats. Containers in which wood alcohol is marketed should have suitable display of labels of warning.

The very selective effect of wood alcohol is shown by the way it poisons specifically only those fibres of the optic nerve which are connected with the *macula lutea* in the retina, the seat of direct and most acute vision, other portions of the retina and optic nerve escaping. In severe cases, total atrophy of the fibres occurs.

**Tobacco.**—When tobacco impairs sight, it is always the result of a combination of several circumstances: (1) adult life; (2) absorption of a large quantity of nicotin, either by smoking, chewing or taking snuff to excess, or by prolonged handling of tobacco by workers in the weed; (3) disturbed digestion which may be an indirect consequence of tobacco abuse; and (4) too free use of alcohol. Individuals vary greatly in susceptibility. The symptoms are dimness of sight and a loss of color sense in central vision. This is the cause of some marine and railroad accidents.

The use of tobacco becomes largely a habit. Few gain the pleasure and solace from it which they crave and expect; on the other hand, tobacco is in no way a help to health. Under ordinary circumstances, smoking three or four moderately strong cigars a day should suffice as a maximum; at least, this amount is not likely to cause trouble with vision.

### ACCIDENTS

**Accidents.**—In New York State about 200 industrial accidents resulting in total blindness occur annually. Besides this, there are a large number of accidents occurring on railroads, in construction work, and in the field and forest.

Many of the accidents to the eyes occurring in factories are pre-

ventable through the use of mechanical guards or goggles. As a rule, the majority of such accidents are due to small flying particles.

A material proportion of blindness is caused by accidents to children at play; sometimes the eyeball is torn by a buttonhook, or pierced by a knife or awl; or a scissors blade, used to untie a knot, slips. Some eyes have been injured by the crack of a whip, by a shot from an air-gun or toy pistol. Accidents also occur to the eyes from fireworks, curling tongs, a child's finger scratching the parent's cornea, or a doll's china head broken into the eyes of its tumbling "mother."

Many cases of blindness were caused by the gases used in the World War.

*Ocular Hygiene*, see page 916.

### TETANUS

(*Lockjaw*)

Compared with the major plagues of man, lockjaw has always been a rare disease. It is on account of the characteristic and fatal spasms that it early attracted attention. The student will be well repaid by a study of the historical development of the theories that have been advanced since the time of Hippocrates to explain the cause of tetanus. These theories mirror the prevailing thought upon the nature of disease as it developed from that of evil spirits, through the humoral theory, the realm of miasms and noxious effluvia, to the germ theory. Tetanus could not escape the rheumatism theory which has been such an alluring catchall for symptoms and diseases difficult of explanation. "Taking cold" was assigned its usual rôle here as elsewhere. When no assignable cause seemed at hand, the disease was given the learned title—idiopathic tetanus.

**Etiology.**—Carle and Rattini,<sup>116</sup> in 1884, first clearly demonstrated the infectious nature of tetanus by inoculating rabbits subcutaneously with pus from a human case of the disease. In the same year, Nicolaier<sup>117</sup> inoculated laboratory animals subcutaneously and saw the tetanus bacillus at the site of injection. In 1889, Kitasato<sup>118</sup> for the first time grew the organism in pure culture, and by successful inoculation experiments proved that this bacillus was the real cause of tetanus. Kitasato further showed that the tetanus bacillus is not found in the heart's

<sup>116</sup> *Giornale della T. acad. di Med. di Torino*.

<sup>117</sup> *Deutsch. med. Wchnschr.*, 1884, No. 52; *Inaug. Diss.*, Gottingen, 1885.

<sup>118</sup> *Deutsch. med. Wchnschr.*, 1889, No. 31; *Ztschr. f. Hyg.*, 1889, VII, 225.

blood of mice dead of tetanus, and therefore concluded that we are dealing with an intoxication, and not bacteremia. We now regard tetanus as a type of the true toxemias; that is, the virus remains localized in the wound, and the soluble toxin does the damage. This work of Kitasato's was one of great importance, and led to the epochmaking discovery of Behring and Kitasato<sup>119</sup> in the following year (1890) upon tetanus and diphtheria toxins and antitoxins, laying the foundation of serum therapy.

Tetanus may be regarded almost solely as a wound complication. All wounds are not equally liable to this complication, even though tetanus spores are present. Punctured, lacerated, and contused wounds are much more susceptible to tetanus than clean-cut or open wounds. The size of the wound is of much less consequence than its character and content. Fatal tetanus may develop from trivial wounds, such as pin scratches, small splinters, insect bites, vaccinations, etc. Necrotic tissue, foreign bodies and other irritants favor the development of tetanus.

Symbiosis is an important factor in tetanus. Wounds infected with the gas bacillus, *vibrion septique*, pyogenic organisms and other bacteria favor anaërobic conditions and permit the tetanus spores to germinate, and seem to encourage the growth of the bacillus and the development of toxin.<sup>120</sup> Tetanus spores washed free of toxin and placed in healthy tissues do no harm, but add a trace of gas gangrene toxin, or a chemical irritant as saponin, or a physical irritant such as a foreign body, and tetanus develops.

Weinberg<sup>121</sup> has shown the multiplicity of anaërobic wound infections, and has also shown how they influence each other. The gas bacillus (*B. perfringens*, also known as *B. Welchii*) plays an auxiliary part in the causation of tetanus. The bacillus of malignant edema (*vibrion septique*) is also an ally of tetanus. Antitoxins against both these spore-bearing anaërobes have been produced. These antitoxic sera, as in the case of tetanus, have prophylactic value, but feeble curative properties. The experience in the war soon taught the usefulness of employing, for the prevention of tetanus, a serum containing three antibodies: (1) against tetanus, (2) against the gas bacillus, and (3) against *vibrion septique*. These are the commonest but not the only infective agents that play a part in stimulating the growth of the tetanus bacillus in wounds. Tulloch<sup>122</sup> on the basis of agglutination tests has separated tetanus cultures into four types. Fortunately, any one of the four antitoxins will neutralize any or all of the four toxins.

<sup>119</sup> *Deutsch. med. Wchnschr.*, XVI, No. 40, p. 1113.

<sup>120</sup> In the laboratory some of the strongest tetanus toxins have been prepared from mixed or contaminated cultures.

<sup>121</sup> *Ann. de l'Inst. Pasteur*, Sept., 1917, XXXI, No. 9, p. 442.

<sup>122</sup> *Proc Royal Soc.*, Series B, April, 1918.

The normal habitat of tetanus is in the intestinal tract of herbivorous animals. Sanchez, Toledo, and Veillon<sup>123</sup> found tetanus in the feces of 4 out of 6 horses and in the feces of 1 of 2 cows. Park found tetanus bacilli in the intestines of about 15 per cent. of horses and calves living in the vicinity of New York City. They are present to a variable extent in the intestines of man; from 5 per cent. up to 20 per cent. in ostlers and dairymen.

It is rather a curious paradox that the horse, which is the most susceptible of all animals to tetanus toxin, is one of the principal hosts of the tetanus bacillus. The intestinal canals of certain animals are perfect anaërobic incubators for the growth of tetanus bacilli; such animals may be regarded as "tetanus carriers."

**Occurrence.**—The spores taken in the food are not affected by gastric digestion, and in the intestines find ideal anaërobic conditions, food supply and temperature for growth and development. Here they multiply and pass in the dejecta to pollute the soil. The soil, therefore, in all regions inhabited by man and domestic animals is more or less contaminated with tetanus. The bacilli, however, do not multiply in the soil. While the soil acts only as a vehicle, it is the immediate source of the large proportion of tetanus in man. The presence of tetanus spores in soil, street dust, fresh vegetables and on clothing and the skin may be traced to fecal contamination.

On account of the great resistance of the spores, they are blown about in dust and are spread everywhere by dirt and manure. Tetanus has been found in hay dust, on horses' hair, in the dust of houses, barracks, and hospitals, in the mortar of old masonry, in street dust, on food, in gelatin, on the skin, and in the greatest variety of places.

One of the agencies in the distribution of tetanus spores over limited areas is undoubtedly the common house fly. The poisoned arrowheads of certain savages in the New Hebrides contain tetanus spores obtained by smearing the arrowheads with dirt from crab holes in the swamps (Le Dantic).

Tetanus bacilli are not equally numerous in all localities. The infection is much more prevalent in warm than in cold countries. It is especially severe in the tropics, yet Iceland at one time suffered severely from tetanus neonatorum. In the United States, tetanus occurs especially in the Atlantic States, and in some parts of Long Island, New Jersey, and the Hudson Valley, which have become noticeable for the number of cases of tetanus complicating small wounds. The soil of Flanders and France has through long cultivation become saturated with the spores of tetanus and other anaërobic. One grain of it from the trenches injected into a laboratory animal invariably produced tetanus. Tetanus spores are widely disseminated in India. Goodrich states that

<sup>123</sup> *La Semaine Méd.*, 1890, X, p. 45.

in Bombay alone there were 1,955 cases of tetanus in five years. These do not include the puerperal cases.

Tetanus occurs either sporadically or in epidemic form. Formerly epidemics in hospitals (especially in lying-in hospitals), and in wars were rather common. The conditions of trench warfare in the World War favored wound complications, and included a frightful amount of tetanus until antitoxin was used as a routine prophylactic in all wounds. Before the days of asepsis the infection was often spread through surgical instruments, fingers, bandages, etc.

The wounds produced by blank cartridges are especially liable to develop tetanus. The source of the tetanus spore in these cases is not entirely clear. Wells examined 200 cartridges from five firms without finding the tetanus bacillus. It is probable that the spore is upon the skin and is carried along with the paper and powder from the blank cartridge. The peculiar character of the wound favors the development of tetanus.

The great decrease in the number of cases of tetanus following Fourth of July wounds is due to the vigorous campaign carried on by the American Medical Association. In 1903 there were 406 deaths from tetanus; in 1904, 91; 1905, 87; 1906, 75; 1907, 73; 1908, 76; in 1911 only 18 cases and 10 deaths and so on until 1916 when no deaths occurred from this cause. Eighty per cent. of these followed blank cartridge wounds. The good results are attributed to the more thorough and careful treatment of the wounds and especially the use of tetanus antitoxin as a prophylactic—and more recently to safer and saner methods of celebration.

Tetanus spores or toxin may contaminate bacterial vaccines, antitoxic sera, vaccine virus, and other biologic products used in human therapy. The possible association of tetanus with bacterial vaccines was demonstrated in the unfortunate outbreak at Mulkowal, India, in 1902.<sup>124</sup> One hundred and seven persons were inoculated with Haffkine's plague prophylactic. Of these 19 were affected with symptoms of tetanus and died. In this case the tetanus probably grew as a contamination in the plague culture, for it is now well known that the anaërobic conditions produced in *B. diphtheriae*, *B. pestis*, *B. subtilis*, and other organisms in liquid culture media favor the growth of tetanus and the development of its toxin.

In St. Louis (1901) diphtheria antitoxin was taken from a horse during the period of incubation of tetanus and used in amounts from 5 to 10 c. c. upon 7 children, all of whom died of tetanus. Bolton, Fisch, and Walden<sup>125</sup> found that the serum was sterile, but contained tetanus

<sup>124</sup> *Jour. Trop. Med. and Hyg.*, 1907, X, p. 33.

<sup>125</sup> Bolton, Fisch, and Walden in *St. Louis Medical Review*, Vol. XLIV, No. 21, Nov. 23, 1910, p. 361.

toxin in considerable amount. If the serum had first been tested upon animals, its poisonous properties would have been discovered. This test is now required by the United States law of July 1, 1902, for all serums and vaccines sold in interstate traffic. As a further precaution against this complication horses undergoing treatment for the production of immune sera are given prophylactic doses of tetanus antitoxin from time to time. Tetanus sometimes occurs as a complication of vaccination. See page 22.

It is, of course, not the rust on a nail that is dangerous, so far as tetanus is concerned, but the spore-bearing dirt it carries into the deep, contused wound that causes the trouble. Gelatin may contain tetanus spores, and the subcutaneous injection of imperfectly sterilized gelatin as a hemostatic has sometimes resulted in accidents.

Tetanus is harmless when taken by the mouth. Susceptible animals may be given enormous doses of tetanus toxin by the mouth without producing the disease. The bacillus and its spore may be regarded as a saprophyte in the intestinal tract. There is, however, a suspicion that tetanus spores sometimes invade the organism through small wounds in the digestive or respiratory tract. Perhaps some of the cases following surgical operations may be accounted for in this way rather than by infection of the catgut used for ligatures.

Tetanus sometimes occurs where no wound can be found. This is the so-called "idiopathic tetanus." One explanation of these cases is to be found in the fact that the spores are numerous in street dust and may enter the respiratory tract. They cannot do harm so long as the mucous membrane is healthy, but may enter through inflamed membranes or through small wounds in the nose.

Tetanus bacilli have been found in the bronchial mucus of idiopathic cases. Tetanus spores have occasionally been found in the lymph glands, liver, and other parts of the body, upsetting our previous view that they are always strictly confined to the site of the wound. The spores may remain latent or dormant in scar tissue or the sequestrum of bone and may be released and start an attack months or years afterwards, thus giving another plausible explanation of some cases of idiopathic tetanus.

Puerperal tetanus was formerly a frequent and serious complication following childbirth, but has been conquered by asepsis.

**Trismus Neonatorum**, or tetanus of the newborn, is still a common and very fatal infection, especially in the tropics. Before the days of asepsis the infection was permitted to enter through the umbilical wound. In certain of the West Indian islands more than one-half of the mortality among the negro children has been due to this cause. In Venezuela, trismus neonatorum is one of the chief causes of deaths, and goes by the name of mocezuelo.

The following figures are taken from official reports:<sup>126</sup>

Year	Population of Venezuela	Total Deaths in Venezuela	Deaths from Infantile Tetanus	Total Deaths from Tetanus, all Forms Except Puerperal Variety
1905	2,598,063	58,100*	.....	3,316

Total.....	.....	617,736	18,201	28,015

\* Infantile tetanus not separated from total of tetanus deaths in years 1905-1908, inclusive.

**Incubation.**—The period of incubation in man is usually from 6 to 14 days. The period is directly proportional to the amount of toxin and the severity of the disease. This can readily be demonstrated upon susceptible animals. In a study of 600 serial tests, Rosenau and Anderson found this direct relation between the period of incubation and the severity of symptoms by the subcutaneous injection of varying amounts of toxin into guinea pigs. Thus guinea pigs receiving fairly large doses showed symptoms on the third day and usually died; when the dose is smaller, the period of incubation is longer, the disease milder, and the chances of recovery greater. In man, with a short period of incubation, 6 days or less, the disease is almost invariably fatal. With longer periods the disease is usually milder and recovery frequently takes place without the use of antitoxin or other measures. Tetanus toxin is absorbed by the terminal nerve endings, and travels up the axis cylinders of the nerves to the cord and brain. It is also distributed in the blood. The period of incubation, therefore, depends somewhat upon the point of entrance of the poison and its proximity to abundant motor nerve endings.<sup>127</sup>

**Resistance.**—The tetanus *bacillus* is readily destroyed by the ordinary agencies that kill vegetative bacteria. It is killed almost at once in contact with the free oxygen of the air. On the other hand, few, if any, forms of life have a greater resistance than the tetanus *spore*. Hours of exposure to 60° or 70° C. do not affect them. They usually survive an exposure of one hour to 80° C., but, as a rule, are killed in

<sup>126</sup> Furnished by Surgeon W. J. Stewart, U. S. Public Health Service.

<sup>127</sup> For discussion of tetanus toxin and tetanus antitoxin, see pages 103, 553 and 568.

streaming steam or boiling water in 60 minutes. Tetanus spores, however, vary greatly in the power to resist the boiling temperature. Kitasato<sup>128</sup> found them to resist 80° C. for one hour, but to be killed in streaming steam in 5 minutes. Vaillard and Vincent<sup>129</sup> found that the spores heated in the presence of moisture in a closed vessel would resist destruction at 80° C. for 6 hours, at 90° C. for 2 hours, and 100° C. 3 to 4 minutes, that they were not always destroyed in 5 minutes, but never resisted more than 8 minutes at 100° C. Levy and Bruus<sup>130</sup> found that destruction begins at 8½ minutes at 100° C.; after 15 minutes few survive, after 30 minutes none. Falcioni<sup>131</sup> studied the subject in view of the dangers of the subcutaneous injection of gelatin. He impregnated gelatin with spores of tetanus bacilli grown in agar or broth for 10 to 12 days, and used Koch's steam sterilizer. He found the spores to resist destruction for 2½, but not for 3, hours in streaming steam.

The experimental results are, therefore, sufficiently varied and conflicting to suggest that races of tetanus bacilli exist, the spores of which vary widely in their resistance to moist heat at 100° C. Theobald Smith<sup>132</sup> found that under certain conditions of cultivation some tetanus spores survive a single boiling or streaming steam regularly for 20 minutes, usually for 40 minutes, and occasionally for 60 minutes; in one case 70 minutes' exposure did not destroy the spores. He also showed the possibility of tetanus spores surviving in culture fluids sterilized by discontinuous boiling or steaming in routine laboratory work for fully 20 minutes on three successive days.

In general, dry spores are more resistant than moist spores; and young spores are often harder to kill than old spores.

Tetanus spores resist the action of 5 per cent. carbolic acid for 10 hours, but are killed in 15 hours. A 5 per cent. solution of carbolic acid, however, to which 0.5 per cent. of hydrochloric acid has been added, destroys them in 2 hours. Bichlorid of mercury, 1-1,000 kills the spores in 3 hours, and in 30 minutes when 0.5 per cent. of hydrochloric acid is added to the solution. According to Park, silver nitrate solution destroys the spores of average resistance in 1 minute in 1 per cent. solution, and in about 5 minutes in a 1 to 1,000 solution. *Tetanus spores are destroyed with certainty when exposed to dry heat at or above 160° C. for one hour, or to steam at 120° C. for 20 minutes. Entire confidence may be placed upon either of these two methods.*

The temperature recorded on the thermometer of the sterilizer may be higher than the actual temperature within the apparatus. Good

<sup>132</sup> *Jour. A. M. A.*, March 21, 1908, Vol. L, pp. 929-934.

sterilizing technic is essential and a factor of safety desirable. The time necessary for penetration must be taken into account. Thus, the government regulations<sup>133</sup> require an exposure of 170° C. for two hours for dry sterilization of glassware intended to contain biologic products. These same regulations require 121° C. (15 pounds) for 30 minutes for steam sterilization of glassware and rubber tubing. Glassware and rubber tubing must be moistened immediately before steam sterilization and each flask or hollow apparatus should contain one-eighth of its volume of water when put in the autoclave. This is for the purpose of insuring that steam will be in contact with all surfaces. In some cases, rubber goods may be sterilized by boiling for 30 minutes in 3 to 5 per cent. phenol or some similar disinfectant.

Direct sunlight does not kill the spores, but seems to diminish their virulence. Under certain circumstances they may live a very long time; Henrijean reports that, by means of a splinter of wood which once caused tetanus, he was able after 11 years again to cause the disease by inoculating an animal with the infective material.

**Prophylaxis.**—*Local Treatment of Wounds.*—Thorough surgical treatment of the wound as soon as possible is the first important measure in the prevention of tetanus. Wounds, however insignificant, should be thoroughly cleansed. Punctured or lacerated wounds, in which there is special danger of tetanus, should be freely opened, and every particle of foreign matter carefully removed. Promptness in cleansing the wound surgically is almost as important as thoroughness. Gunshot wounds and wounds containing garden earth, street dust, or other material liable to contain tetanus spores should receive special consideration. All necrotic tissue, or tissue likely to die, must be removed. The experience of the war demonstrated that thorough excision of the wound (débridement) is good practice. Germicides are useless—the surgeon's knife is the best antiseptic. The division of the umbilical cord and the treatment of the navel in the newborn must be done under the strictest asepsis. Wounds in which there is suspicion of tetanus should be kept open and freely drained, and otherwise treated so as to discourage anaërobic conditions.

Tetanus spores gain entrance into wounds not only from manure, garden soil, street dust, and similar sources, but also from the hands, instruments, bandages, suture material, or other objects. It is important to remember that the tetanus spore is exceedingly resistant to heat and chemical agents, and that in surgical and obstetrical practice confidence should not be placed simply upon brief boiling to destroy the spores. Very particular care must be exercised in the disinfection of substances injected into the body, such as gelatin and other organic materials.

<sup>133</sup> Regulations of the U. S. Public Health Service, Oct. 1, 1919.

*Specific Prophylaxis.*—Tetanus antitoxin is a specific and trustworthy preventive. The great experience of the war adds confirmation to the protective power of this specific and sovereign serum. Its use, however, must be understood to achieve satisfactory results. The antitoxin must be administered before the advent of symptoms, for after the tetanus toxin has combined with the motor nerve cells in the central nervous system it can neither be displaced nor neutralized with antitoxin. In such cases the most that the antitoxin can do is to combine with and neutralize the free toxin and thus prevent further damage.

From 500 to 1500 units of tetanus antitoxin are used as a prophylactic dose.<sup>134</sup> The amount varies with the severity of the wound and the hazard of tetanus. In wounds liable to infection, the injection should be repeated every seven days until the wound is clean, or the danger passed. It is important to remember that the tetanus antitoxin is eliminated or otherwise disposed of in the body in the course of 10 days or 2 weeks. Therefore, in cases in which the wound does not heal well, as a result of mixed infection, or for other reasons, it is desirable to repeat the injection. This may be done at intervals of 7 or 8 days as long as the danger persists. Occasionally tetanus bacilli persist in the pus-infected tissues, and, when the injected antitoxin has been exhausted, there may occur a late development of tetanus. Instances in which 1,500 units of tetanus antitoxin, repeated if necessary, have failed to prevent the development of tetanus are rare. During the latter part of the war, a triple antitoxin, made from the tetanus bacillus, the gas bacillus<sup>135</sup> (*B. perfringens*), and the bacillus of malignant edema (*vibrio septique*), was used as a routine prophylactic, and resulted in preventing much suffering and saving many lives.

Gunshot wounds and wounds produced by blank cartridges should always be regarded as suspicious, and should be given careful local treatment, supplemented with a prophylactic injection of antitoxin. Tetanus was a frequent complication of trench foot, and therefore a prophylactic injection of antitoxic serum should be given and repeated at intervals of seven days until the wounds are healed.

The prevention of tetanus complication of vaccine wounds consists in: (1) The use of a reliable vaccine which has been biologically tested in accordance with the federal act. (2) Proper methods of vac-

<sup>134</sup> As soon as symptoms appear 20,000 units or more of tetanus antitoxin should be introduced directly into the circulation by intravenous injection; some antitoxin may also be injected into the nerves leading from the wound. Nicolle has obtained favorable results with antitoxin, even after symptoms have developed, by injecting 3 to 5,000 units into the spinal canal, 10,000 units intravenously, and 10,000 units subcutaneously. (*Jour. A. M. A.*, LXIV, 24, June 12, 1915, p. 1982.) In tetanus, as in diphtheria, time is the important element. A few units introduced early are worth more than thousands late.

<sup>135</sup> Bull, C. G., and Pritchett, I. W.: "Toxin and Antitoxin of and Protective Inoculation against *Bacillus Welchii*." *Jour. Exp. Med.*, XXVI, No. 1, July, 1917, p. 119.

cination to avoid unnecessary scabs and anaërobic wound conditions.  
(3) Surgical asepsis of the operation and after-treatment.

Tetanus and other wound infections may be avoided, in those exposed to accidents, by cleanliness of body and clothing. A bath before a battle is a reasonable protection said to be adopted in the Japanese Army and Navy. The common experience of mankind teaches that most wounds heal without tetanus, and that tetanus is, in fact, a relatively rare infection. The physician, however, is in no case justified in taking chances, and it is one of the duties of the medical profession to teach the public that it pays to thoroughly cleanse and care for wounds, however trivial, *at once*, and in accordance with modern methods.

## CHAPTER II

### DISEASES SPREAD LARGELY THROUGH THE ALVINE DISCHARGES<sup>1</sup>

#### TYPHOID FEVER

(*Typhus Abdominalis*)

Typhoid fever is a sanitary problem of first magnitude, especially in this country, where it is still unduly prevalent. In the United States typhoid fever for a long time stood fourth on the list of mortality tables: tuberculosis coming first, then pneumonia and cancer; typhoid fever has now been reduced to about ninth place. The average case fatality from typhoid fever being nearly 10 per cent., it would, therefore, take higher rank on the morbidity tables. In 1910 there were 25,000 deaths from typhoid fever in the United States, representing at least 250,000 cases—one person in every 400. Marked improvement began to occur about 1910, and from that time on nearly every year has witnessed a fall in the typhoid death rate. For about 27,000,000 people in 60 cities of the United States, in 1919 it reached the exceedingly low point of 4.2.

Our general attitude toward typhoid fever is inconsistent; familiarity has bred a remarkable indifference to the disease. Every case of typhoid fever means a short circuit between the alvine discharges of one person and the mouth of another. The physician has a dual duty in the care of a case of typhoid fever: one is to assist the patient, the other is to protect the community. On the other hand, the people should learn the lesson that a case of typhoid fever must be regarded as seriously as a case of cholera. These two diseases present many features in common. Both are intestinal infections of bacterial nature; in both diseases the alvine discharges contain the microorganisms which infect another person when taken by the mouth. Both diseases prevail especially in hot weather, and both diseases are peculiar to man, so that the patient is the fountainhead of each infection. Water, food, fingers, flies, contacts and carriers play a similar rôle in both instances. In the case of cholera the dread of the disease is an important factor in keep-

<sup>1</sup>The control of this group of infections is one of the most notable achievements in preventive medicine. The cause, mode of transmission, and prevention are well understood in theory and readily attainable in practice. Sanitation here finds its first fruitful field, hygiene its useful lessons, and immunology its special application.

ing it out of the country or in preventing its spread when once introduced. By strange contrast, there is a remarkable indifference to typhoid fever. A wholesome fear of typhoid fever would materially assist the health authorities in combating what may be considered one of the major sanitary problems of the age. From the standpoint of preventive medicine, it is proper to regard an outbreak of typhoid fever as a reproach to the sanitation and civilization of the community in which it occurs. When the matter is better understood health authorities will be held responsible for this and other preventable infections, just as some one is now held responsible for preventable accidents.<sup>1a</sup>

Much harm has been done by insisting that typhoid fever is infectious, but not contagious; it is both—that is, communicable.<sup>2</sup>

Typhoid fever occurs both in endemic and epidemic forms. It may truly be regarded as pandemic. Normally, typhoid fever is a warm weather disease. It recurs as an annual crop from July to October.<sup>3</sup> Epidemics caused by infected water occur especially in cold weather. Milk outbreaks may occur at any time of the year. Autumnal typhoid is due partly to infection contracted at "health" resorts, and has, therefore, been called a vacation disease.

Typhoid fever is more prevalent in rural districts than in cities. In the United States there is more typhoid fever in the southern states than in the northern zone. The only explanation to account for this is the influence of temperature, rural conditions, and association with the negro. Typhoid fever is no respecter of rich or poor; it attacks those in robust health, all ages, both sexes.

The period of incubation is usually 7 to 23 days, commonly about 10 to 14 days.

Typhoid fever is a disease which ordinarily attacks the individual during the period of greatest economic value to the community. The economic loss, therefore, is appalling, and has been estimated to reach the sum of no less than \$100,000,000 annually in the United States. Again, typhoid fever is an infection against which the individual alone cannot protect himself wholly without the aid of the community.

The control of typhoid fever in modern armies and the marked reduction in its prevalence in the civilian population in the United States in recent years is one of the great triumphs of preventive medicine.

**Historical Landmarks.**—Typhoid fever was confused for centuries with other continued fevers, such as recurrent fever, septic infections, and typhus fever. The first full description of what was probably typhoid fever was written by Thomas Willis, an English physician, who, in 1643, described an epidemic that occurred in Parliamentary troops. Breton-

<sup>1a</sup> See Vennen vs. New Dells Lumber Co., page 1291.

<sup>2</sup> For distinction between these terms see page 463.

<sup>3</sup> In the southern hemisphere the typhoid season is during our winter.

neau in 1826 further described the clinical characteristics and called it "dothienenteritis," or abscess of the small intestine, a name it frequently bears in French literature. Louis, the distinguished French clinician, in 1829 gave the name typhoid fever to the malady to distinguish it from typhus fever. William Gerard, of Philadelphia, a pupil of Louis, showed the difference in the lesions between these two fevers, which established typhoid fever as a distinct disease.

William Budd in 1856 pointed out that the disease is transmitted by the patient's excreta. He stated that: "The living human body, therefore, is the soil in which this specific poison breeds and multiplies; and that most specific of processes which constitutes the fever itself is the process by which the multiplication is effected." The first water-borne outbreak carefully studied and described was at Lausanne, Switzerland, in 1872; the first water-borne outbreak to attract attention in the United States occurred in Plymouth, Pennsylvania, in 1885. In 1873, Murchinson traced an epidemic to a contaminated milk supply. Eberth in 1880 saw the *Bacillus typhosus* in the tissues, and four years later Gaffky grew it in pure culture. Metchnikoff and Besredka, in 1900, finally established the etiological relation by producing the disease in anthropoid apes with pure cultures. In 1894, Pfeiffer and Kolle first gave small subcutaneous inoculations of dead typhoid bacilli. About the same time, and independently, A. E. Wright began similar inoculations in British soldiers, but it took something over 10 years to establish the prophylactic value of typhoid vaccines.

**Prevalence.**—Typhoid fever prevails more or less in all countries—the amount of the disease, however, varies greatly. It appears to be a disease of defective civilization, for those communities paying least attention to sanitation, as a rule, suffer most. In the United States there are comparatively few communities of 1,000 inhabitants or more which, during any period of twelve consecutive months within the last decade, have been entirely free from typhoid fever. According to the United States census report for 1900, the average typhoid death-rate in the United States was 46.5 per 100,000 inhabitants. In 1917, this was reduced to 13.4.

The improvement in the situation within recent years is shown by the following rates per 100,000 of population for the registration areas:

1910 .....	23.5
1911 .....	21.0
1912 .....	16.5
1913 .....	17.9
1914 .....	15.4
1915 .....	12.4
1916 .....	13.3
1917 .....	13.4

A still greater lowering of the typhoid rates in our large cities is shown in table, page 109. In 1908 the death toll from typhoid fever was no less than 35,000 in the United States. In other words, one person in about 300 in the United States contracted typhoid fever that year. It is estimated that in 1910-11 the number of deaths was reduced to about 25,000.

The significance of these figures may be judged by estimating the probable number of cases of typhoid fever among persons handling the milk supply. Take, for instance, a city, as Washington, receiving its milk from a thousand dairy farms. On the average there will be about four persons on each farm who in one way or another come in contact with the milk. That makes 4,000 persons among whom about 20 cases of typhoid may be expected to occur annually. Add to this the carriers, and it is no wonder that milk-borne outbreaks of typhoid fever are frequent occurrences.

The rate of prevalence of typhoid fever in the United States in comparison with the rates of many other countries was very high. Thus, the annual death-rate from typhoid fever per 100,000 population for the period 1901-1905 was: in Scotland, 6.2; in Germany, 7.6; in England and Wales, 11.2; in Belgium, 16.8; in Austria (1901-1904), 19.9; in Hungary, 28.3; in Italy, 35.2; while the rate in the United States during the same period was about 46.5. A great improvement in the typhoid situation is now taking place in this country—and many states and cities are reporting figures approaching and even bettering the European rates. In 1917, the rate in the registration area of the United States was 13.4, a reduction of 63 per cent. since 1900.

In northern Europe the 33 principal cities, with an aggregate population of 31,500,000, had an average typhoid death-rate per 100,000 population of 6.5 in 1909 and 1910. This includes such a notorious typhoid center as Petrograd, which had a rate of 33.7 in 1910. The high rate in Petrograd was due to the water supply, which is partly filtered and partly raw Neva water.

A comparison of these rates with typhoid fever in America is given in Table 2, page 109.

The typhoid rates in our larger cities are coming down, owing to safer water supplies, better sanitary conditions and the increasing use of typhoid vaccines. In fact the improvement in our typhoid situation is one of the great sanitary reforms now going on. This improvement is shown in the table on the following page, which gives the death rates in the large cities of the United States.

**Residual or "Normal" Typhoid.**—When a city, such as Albany, Chicago, Lawrence, Lowell, or Pittsburgh, which had been using grossly polluted water, is furnished with a water supply of good sanitary quality, there at once results a marked reduction in the amount of typhoid

ANNUAL DEATH RATES FROM TYPHOID FEVER PER 100,000 POPULATION IN 50 CITIES OF THE UNITED STATES HAVING MORE THAN 100,000 INHABITANTS

Official figures kindly furnished by Richard C. Lappin, Chief Statistician, Division of Vital Statistics, Bureau of the Census, U. S. Dept. of Commerce.

fever. The curve is not only lowered, but it is also changed in character. The remaining typhoid after the water-borne infection has been removed is known as residual typhoid, and the curve in such cases is spoken of as the "normal" typhoid curve. The normal curve shows a distinct summer prevalence recurring with marked uniformity each year, and lacks the great irregularities which characterize the curve of a community drinking badly infected water. Normal typhoid is endemic typhoid; Sedgwick has proposed the name "prosodemic" (*proso*, through, and *demos*, the people) as more expressive of this type of the disease. The amount of residual typhoid varies markedly in different localities; thus, it is twice as high in the southern as in the northern part of our country. Residual typhoid should not exceed 5 deaths per 100,000 pop-

ulation. It is due to carriers, milk, other food, contacts, flies, etc., and may be controlled by sanitary housecleaning.

**Channels of Entrance and Exit.**—The typhoid bacillus probably always enters by the mouth. Typhoid fever is generally regarded as primarily a gastro-intestinal infection, although the disease itself is not produced unless the blood, glands, and other structures of the body are invaded with the specific microorganism. The disease is now regarded as primarily a blood infection or bacteremia. The typhoid bacillus grows and multiplies in the intestinal tract, penetrates the mucosa, and thus invades the body. The bacilli leave the body mainly in the feces and urine, occasionally in the sputum and other discharges. Typhoid bacilli appear in the feces early in the disease; sometimes before the fever. Later in the disease they diminish in number and usually disappear during convalescence, although they may continue indefinitely (see *Bacillus Carriers*). The feces may contain only a few typhoid bacilli; usually they are present in considerable numbers; occasionally practically replacing the colon bacillus.

Typhoid bacilli commonly appear in the urine about the second, third, or fourth week. They grow well in this fluid both within and without the body, and may be present in such enormous numbers that the urine resembles a 24-hour-old bouillon culture. From the standpoint of prevention, it is very important not to neglect the virus in the urine. Hexamethylenamin in ten-grain doses or more, three times a day, diminishes the frequency of typhoid bacilluria. This drug is eliminated as formaldehyd, provided the urine is acid, and is therefore not effective in an alkaline urine.

The sputum ordinarily does not contain the bacilli unless there is a pneumonia or severe bronchitis. Gould and Quales, and also Purjesz and Perl,<sup>4</sup> have found typhoid bacilli in about 50 per cent. of the cases by rubbing the gums, tonsils, and tongue of patients suffering with typhoid fever. The microorganisms from the mouth were found as late as the fourth to eighth week of convalescence. These findings are important from the standpoint of diagnosis and prevention. The bacilli may be eliminated with the discharges from suppurating middle ears; from abscesses, such as periostitis, months and even years after the disease.

**Diagnosis.**—An early diagnosis of typhoid fever is essential for the successful treatment of the patient, and is of vital importance in controlling the spread of the infection. Early diagnosis can only be assured through laboratory methods. Typhoid bacilli may be readily isolated from the blood, the feces, or the urine.

**Blood Cultures.**—Probably the easiest method, as well as the one giving the maximum information, is through blood cultures. The taking of a little blood for this purpose is no more difficult or annoying

<sup>4</sup> *Wien. klin. Woch.*, 1912, XXV, 1494.

to the patient than swabbing the throat for diphtheria. A few drops of blood may be obtained by puncturing the lobe of the ear or the finger, with the usual precautions to prevent bacterial contamination. A much better method, however, consists in withdrawing 5 to 10 c. c. of blood by means of a syringe from one of the veins at the bend of the elbow. The technic is very simple, and, if the needle is sharp, the patient scarcely feels the puncture. The blood may be planted in bouillon, or in bile. After 24 hours in the incubator, any growth that occurs is transplanted to Endo's medium, colonies isolated, and tested for agglutination. Often a pure culture is obtained in the first medium, so that the diagnosis may be established in 24 hours—at most, in 2 or 3 days.

Typhoid bacilli appear in the blood early in the disease, perhaps occasionally during the prodromal symptoms. Kayser obtained positive results from 90 per cent. in the first week, 65 per cent. in the second, 42 per cent. in the third, 35 per cent. in the fourth. Our results in Washington were approximately the same. The typhoid bacilli probably do not grow in the blood during life. Their presence in the blood stream represents an overflow from the spleen and lymphatic tissues. The presence of typhoid bacilli in the blood may be taken to mean typhoid fever. The same cannot always be said if they are found in the feces or urine.

*The Feces.*—From the feces or urine typhoid bacilli are best isolated upon Endo's medium.<sup>5</sup> This consists of a 4 per cent. alkaline agar containing fuchsin, which has been decolorized with sodium sulphite. Upon the surface of this medium typhoid colonies appear in 24 hours as translucent, dewdrop-like colonies, whereas colon bacilli and other organisms that produce acid and split the fuchsin appear as red colonies. Suspicious colonies are fished and may be tested at once under the microscope for agglutination, or may be planted in bouillon to obtain a growth sufficient for macroscopic agglutination tests. In any critical case pure cultures should be obtained and studied for morphological, cultural, and other biological characters. The specimen of feces may be preserved hours or days by placing it in glycerin,<sup>6</sup> one part of feces to 2 parts of 30 per cent. glycerin. This percentage of glycerin has the further advantage of keeping down *B. coli* and other associated bacteria.

*Technic.*—Make plain, nutrient, sugar-free agar as follows: Tap water (cold), one thousand cubic centimeters; powdered agar, fifteen grams; peptone (Witte), ten grams; meat extract (Liebig), three grams. Cook in double boiler one hour. Make the reaction just alkaline to litmus by the cautious addition of NaOH. Cook fifteen minutes to set the reaction, and then filter through absorbent cotton.

<sup>5</sup>Other useful media are: Drigalski-Conradi, Krumwiede or Russell's double sugar.

<sup>6</sup>Teague and Clurman: *Jour. Inf. Dis.*, XVIII, 6, June, 1916, p. 653.

The tap water should be as cold as possible and the agar should be "dusted" on the surface and allowed to settle into the medium before heat is applied and before the other ingredients are added.

After filtration, the medium is stored in flasks containing known amounts, conveniently in one hundred-cubic-centimeter lots, and sterilized in the autoclave.

To use the medium: (a) Prepare a ten per cent. solution of fuchsin in ninety-six per cent. alcohol. (b) Prepare a ten per cent. solution of sodium sulphite in water.

Add one cubic centimeter of (a) to ten cubic centimeters of (b) and heat in the Arnold sterilizer for twenty minutes = (c).

Add one per cent. of lactose (which must be chemically pure) to the agar medium described above, and heat in the Arnold sterilizer until the medium is melted and the lactose thoroughly distributed in it. The decolorized fuchsin solution (c) is then added in the proportion of one cubic centimeter of the mixture to each one hundred cubic centimeters of medium; then thoroughly mixed.

Plates are then poured and allowed to harden (with the covers removed) in the incubator for thirty minutes, after which time they are ready for inoculation.

*Preparation of Feces for Inoculation.*—The feces are collected preferably in the small rectal tubes described by Kendall.<sup>7</sup> A small portion of feces (about a loopful) is thoroughly emulsified in ten cubic centimeters of sugar-free broth, and preferably incubated one hour at 37° C. prior to the inoculation of the plates. This preliminary incubation does two things: the clumps of bacteria settle down, leaving a more uniform suspension of bacteria in the supernatant fluid for inoculation, and these bacteria undergo a slight development in a medium particularly suited for their growth. The thin suspension of the stool is now rubbed upon the surface of the agar plates by means of a bent, sterile, glass rod, and the plates incubated for 18 hours at 37° C. The suspicious translucent, colorless colonies are removed entire to small test tubes containing one cubic centimeter of broth and incubated for two hours at 37° C. At the end of this time there will be sufficient growth to make the customary microscopic agglutination tests. Confirmatory cultural characters may be obtained by inoculating suitable media from the same tubes as those from which the organisms for agglutination were obtained.

Physicians should encourage boards of health to furnish diagnostic aids of a laboratory nature. Such work should be in the hands of specialists rather than entrusted to those who make occasional analyses. Early and accurate diagnosis is just as important to prevent the

<sup>7</sup> *Boston Med. and Surg. Jour.*, CLXIV, No. 1, Sept., 1911.

spread of other communicable diseases as it is with typhoid. These facts emphasized here will not be repeated under each disease.

**Bacillus Carriers.**<sup>7a</sup>—About 33 per cent. of cases continue to discharge typhoid bacilli for three weeks after the onset of the disease, and about 11 per cent. for 8 to 10 weeks; these are known as *convalescent* carriers. From 2 to 4 per cent. of all cases continue to discharge typhoid bacilli indefinitely; these are *chronic* or permanent carriers. Typhoid bacilli are found in the stools of some persons without a clinical history of having had the disease; these are *passive* carriers, also called healthy or normal carriers. Albert states that 25 per cent. of all chronic typhoid carriers have never had typhoid fever, and further estimates that 1 in every 1,000 of the general population is a carrier. In our Washington studies,<sup>8</sup> we found 0.3 per cent. of the population in 1908 to be temporary passive carriers. At the Strassburg Station (1903-5) Klinger reported 11 or 0.64 per cent. of 1,700 healthy individuals to be temporary passive carriers, and 12 to be permanent carriers. In my laboratory at Harvard, specimens from over 2,000 healthy persons were examined in 1917, with only one typhoid carrier—a man who had the disease several years before. The per cent of carriers naturally varies with time, place, personnel, and prevalence of typhoid fever.

Women outnumber men as carriers about 4 to 1. About 80 per cent. of all chronic carriers and about 60 per cent. of temporary carriers are females. Women are more subject to inflammation of the gall-bladder and to gall stones, and it is now well understood that typhoid bacilli localize and maintain themselves in the gall-bladder and bile ducts. The gall-bladder is the source of the fecal typhoid bacilli found in carriers. Children are less subject to gall-bladder disease, and therefore seldom become carriers. The significance of these facts is of importance in looking for carriers, special attention being given to women who have or have had symptoms, however slight, in connection with the gall-bladder or liver. The remarkable tendency of women to become carriers is particularly hazardous when we bear in mind their intimate association with the handling and preparation of food.

Typhoid carriers are either *fecal* or *urinary*, or both; the former is more frequent than the latter, and apparently also more dangerous; that is, most outbreaks of typhoid fever traced to carriers turn out to be individuals who discharge typhoid bacilli in the feces rather than in the urine.

It seems that some carriers are more dangerous than others. This is due partly to personal habits, partly to opportunity to infect food and drink, and partly to the virulence of the organism. Further, carriers are quite irregular in the elimination of typhoid bacilli.

<sup>7a</sup> See also pages 401-2.

<sup>8</sup> Rosenau, Lumsden and Kastle: *Hyg. Lab. Bull.*, No. 52, U. S. Public Health Service, p. 124.

Typhoid carriers in dairies have been responsible for many outbreaks. A carrier employed as a cook, waiter, nurse, or in a dairy is a special menace. A very large percentage (from 5 to 40 per cent.) of cases of typhoid fever have been traced to carriers. Carriers have a greater opportunity to spread the infection than bed-ridden cases. The amount of harm which a single individual can cause is amazing.

The story of "TYPHOID MARY" was the first of its kind to be reported<sup>9</sup> in America, and has become a classic. Mary Mallon was a cook in a family for three years, and in 1901 she developed typhoid fever. About the same time a visitor to the family had the disease. One month later the laundress in this family was taken ill.

In 1902, Mary obtained a new place, and two weeks after her arrival the laundress was taken ill with typhoid fever. In a week, a second case developed, and soon seven members of the household were sick.

In 1904, the cook went to a home on Long Island. There were four in the family, besides seven servants. Within three weeks after her arrival, four servants were attacked.

In 1906 Mary went to another family, and six of the eleven members of this family were attacked with typhoid between August 27th and September 3rd. At this time, the cook was first suspected. She entered another family on September 21st, and on October 5th the laundress developed typhoid fever.

In 1907, she entered a home in New York City and two months after her arrival two cases developed, one of which proved fatal. During these five years, "Typhoid Mary" is known to have been the cause of twenty-six cases of typhoid fever.

She was virtually a prisoner by the New York Department of Health in a hospital from March 19, 1917. Cultures taken every few days showed bacilli on and off for three years. Sometimes the stools contained enormous numbers of typhoid bacilli, and again for days none could be found.

"Typhoid Mary" then escaped from observation until 1914. In October of that year, she was engaged as cook in the Sloane Hospital for Women in New York. In January and February of 1915, an outbreak of typhoid occurred, principally among the doctors, nurses and help of the institution, involving twenty-five cases. The cook was suspected, but she left the premises on a few hours' leave, and did not return or leave her address. She was, however, located by the Health Department under an assumed name, and an investigation established her identity as the famous "Typhoid Mary."

A subsequent study of her career showed that she had infected still other individuals beyond those already mentioned, and that she may

<sup>9</sup> *J. A. M. A.*, June 15, 1907, XLVIII, p. 2019. Military Surgeon, July, 1919, —a review of the facts by Geo. A. Soper.

have given rise to the well known water-borne outbreak of typhoid in Ithaca, New York, in 1903, involving over 1,300 cases (see page 1177). The fact is that a person by the name of Mary Mallon had been employed as a cook in the vicinity of the place where the first case appeared, and from which contamination of the water supply occurred.

Sawyer<sup>10</sup> reports a very instructive history of a typhoid carrier (H. O.) responsible for several outbreaks. The carrier was carefully studied over a period of several years, during which time he infected thirty persons, five of whom died. Frequent examinations of feces of this carrier gave negative results for four months after he had been treated with autogenous typhoid vaccines; nevertheless, he infected three persons when subsequently released from quarantine on parole. The removal of the gall-bladder failed to cure H. O., for typhoid bacilli were found in the feces several times after the operation. It is particularly noteworthy that 41 successive examinations of feces during a period of fourteen months all proved negative, yet the typhoid bacillus was finally isolated from the stomach contents containing bile. This carrier, on account of the virulence of the organism, or careless personal habits, is unusually dangerous and represents a class that should be controlled by quarantine or close supervision. He further illustrates the saying "once a carrier, always a carrier," which seems to be true of chronic typhoid carriers.

Another instructive outbreak caused by a carrier is reported by Sawyer<sup>11</sup> in which 93 cases of typhoid fever occurred in Hanford, Cal., as a result of infected food served at a public dinner. The vehicle of infection was a large pan of spaghetti prepared by a carrier. This dish was baked after it had been infected, but this baking was shown by laboratory experiments to have incubated the bacteria instead of disinfecting the food.

The *Widal* reaction is present in the blood of about 60 to 75 per cent. of typhoid bacillus carriers. It is, therefore, of value as a preliminary test in the epidemiological search for carriers. In blood testing for this purpose dilutions of 1:50 and 1:25, and even a titer of 1:10, may be used. The test should be made with both *B. typhosus* and *B. paratyphosus*  $\alpha$  and  $\beta$ . The bacilli should then be searched for in the urine and feces of those giving a positive reaction. It should be remembered that about 90 per cent. of persons immunized with typhoid vaccine will give a positive agglutination reaction, and that on the other hand it may be very weak in a carrier.

The question of preventing the spread of the disease through bacillus carriers is important and difficult. Surgical methods fail to cure carriers, for the typhoid bacillus may continue to grow in the bile ducts after removal of the gall-bladder, and perhaps also in the small intes-

<sup>10</sup> *Jour. A. M. A.*, June 19, 1915, LXIV, 25, p. 2051.

<sup>11</sup> *Jour. A. M. A.*, Oct. 31, 1914, LXIII, 18, p. 1537.

tine. Nichols, Simmons and Stimmel<sup>12</sup> believe that the so-called urinary typhoid carriers are really kidney carriers, and can be cured by nephrectomy; that intestinal carriers are really bile passage carriers of two kinds: (a) cases in which the gall-bladder alone is infected and which can be cured by cholecystectomy, and (b) cases in which gall-bladder and bile passages are both infected, and which cannot be cured by surgical measures.

Medical measures, such as hexamethylenamin, are efficient for bacilluria, but are of no avail in the fecal carriers. Attempts have been made to relieve the condition by the use of bacterial vaccines. Petruschky<sup>13</sup> and also Meader have reported encouraging results, especially with the use of autogenous cultures. Hektoen suggests the use of kaolin, which acts by adsorption. Most cases resist all attempts to relieve the condition. It is unnecessary to place bacillus carriers *incommunicado*. It is sufficient to restrict their activities so that they cannot infect food or their surroundings. With proper care and cleanliness typhoid carriers may present little danger to their fellow men. This, however, requires intelligence and conscientiousness. The problem, at present, is to detect the carriers, so as to establish a sanitary isolation, if not an actual quarantine. See Recognition of Carriers, page 111.

A chronic carrier should never be allowed to handle or prepare food, even though a number of consecutive examinations prove negative. The intermittent and irregular character of the carrying state should be borne in mind. Gregg reports a carrier who had typhoid fever 52 years before, and Bolduan and Noble one of 46 years standing, who then caused a large milk-borne outbreak. Compulsory control of irresponsible carriers is essential. The prevention and cure of the carrying state is one of the practical and rewardful problems for research.

**Resistance of the Virus.**—The typhoid bacillus has no spore. It is, therefore, comparatively easy to destroy. The only difficulty presenting itself is getting at the bacillus when imbedded in fecal masses. When dry, most typhoid bacilli die in a few hours; occasionally a few survive for months. The fact that typhoid bacilli are killed by drying renders infection through dust unlikely.

When a moist medium, such as water, milk, or urine, is heated to 60° C., practically all the typhoid bacilli such a medium may contain are killed. An exposure at 60° C. for 20 minutes will surely kill all of these microorganisms. They are not destroyed by freezing. See Relation to Ice, page 1184 *et seq.*

In their resistance to germicides typhoid bacilli behave like the average non-spore-bearing bacilli. Thus, bichlorid of mercury, 1-1,000;

<sup>12</sup> *Jour. A. M. A.*, Aug. 30, 1919, Vol. LXXIII, No. 9, p. 680.

<sup>13</sup> *Deut. med. Wochschr.*, July 11, 1912, XXXVIII, 28.

phenol  $2\frac{1}{2}$  per cent.; formalin, 10 per cent., are effective upon the naked germs. In order to kill the typhoid bacilli in feces special precautions or stronger solutions are necessary (see page 1432).

The viability of typhoid bacilli in feces is very variable, depending on the composition of the feces and the varieties of other bacteria present. Sometimes the typhoid bacilli in feces perish in a few hours, often in a day; under certain circumstances they may live for much longer periods. In the Plymouth epidemic typhoid bacilli probably remained alive and virulent in the feces, exposed to the winter's cold, for several months. Levy and Kayser found that they remained alive in feces for 5 months in the winter. The life of the organism in privies and in water is usually comparatively short. In nature they seldom if ever live in water beyond 7 days, and are often dead in 48 hours. They probably live longer in clean water than in contaminated water. In the outer world antibiosis plays an important part, also the presence of deleterious chemicals, temperature, light, desiccation, sunlight, and other factors known to be injurious to spore-free bacteria. As a rule, the typhoid bacillus does not survive long in the soil under the usual conditions.

**Typhoid Bacillus in Nature.**—The typhoid bacillus should be regarded as a pathogen, not as a saprophyte. It lives and grows principally in the human body. It has a tendency to die in water, air, soil, upon fomites, or in nature generally. The grand exception to this statement is in the case of milk, in which the typhoid bacillus grows well.

The typhoid bacillus may live 12 days in crude sewage (Firth); 14 days in a septic tank (Pickard); 4 months in butter (Balley and Field); 5 days in home-made cheese (Heim); 12 days in pot cheese (Lemke); 39 days in ice cream (Mitchell). It is destroyed in 24 hours in milk, butter-milk, whey or butter having an acidity of 0.3 to 0.4 per cent. Krumwiede and Noble found that with a moderate contamination, typhoid bacilli are killed in sour cream in about four days.

In endemic centers the typhoid bacillus is much more widely distributed in man than the cases indicate. Thus, in the District of Columbia, of 1,000 healthy persons examined during the typhoid season of 1908, typhoid bacilli were found in the feces in 3 instances.<sup>14</sup> At least one and perhaps two of these individuals were regarded as temporary carriers. In each instance the organisms were found only once. The population of the District of Columbia in 1908 was 300,000, and at the ratio of 1 per 1,000 this would represent about 300 healthy persons in that community harboring and shedding typhoid bacilli for a brief period of time during the typhoid season.

<sup>14</sup> Rosenau, Lumsden and Kastle: *Hyg. Lab. Bull.*, No. 52, U. S. P. H. S.

## MODES OF SPREAD

Typhoid fever is spread from cases and carriers both by direct or indirect contact—indirect through water, milk, milk-products, oysters, and other foods; also flies, fingers, and fomites. Each of these modes of spread needs separate consideration.

Man is the source of the infection, and the disease must be fought in the light of an infection spread directly and indirectly from man to man.

**Water.**—Water-borne typhoid is a common occurrence. Not long ago it was regarded as the sole or usual mode of spread; now we know that this was a mistake. Most fecal matter ultimately finds its way to water; most water courses draining inhabited regions are contaminated with human feces. Surface water is, therefore, apt to contain typhoid bacilli. The fact that there may be no clinical case of typhoid fever in the drainage area is no guarantee that the water may not be infected—in view of the prevalence of missed cases and bacillus carriers.

Fortunately, typhoid bacilli do not grow and multiply in water under natural conditions. They usually die in a few days, and rarely persist longer than 7 days. They succumb more quickly in some waters than others, more quickly in summer than winter. Ruediger<sup>15</sup> has shown that typhoid bacilli disappear much more rapidly from polluted water during the summer months than during the winter months when the river is protected with a covering of ice and snow.

Water plays a large but diminishing rôle in the spread of typhoid fever. The great water-borne epidemics have overshadowed the other modes of communication. We know that the larger part of the typhoid now prevalent in this country is not water-borne; Whipple in 1908 estimated it at 35 per cent.; it is now certainly much less. Typhoid fever may be excessively prevalent, even epidemic, in a city having a water supply of good sanitary quality.

In the vast majority of cases water-borne typhoid is contracted from a surface supply, that is, a river, small stream, pond, or lake. Ground water becomes a source of danger only under special conditions, especially in limestone regions. See chapter on Water.

Water-borne epidemics present certain definite characteristics. They almost always occur in the spring, fall, or winter, when the water is cold. Most of the great water-borne epidemics have occurred in northern cities, both in this country and in Europe. They usually have a sharp onset, the curve rises to a peak, and declines rapidly. The pollution is usually nearby; that is, there is a *rather direct transfer of fresh virulent infection*. Granting that the typhoid bacillus does

<sup>15</sup> *Jour. Am. Pub. Health Assn.*, June, 1911, Vol. I, No. 16, p. 411.

TYPHOID FEVER, 1902 TO 1916  
(Death Rate per 100,000 of Population)

THE MORRIS PETERS CO., WASHINGTON, D. C.

FIG. 11.—INFLUENCE OF PUBLIC WATER SUPPLIES ON THE TYPHOID FEVER DEATH RATE

(Diagram prepared by Marshall O. Leighton, U. S. Geological Survey, from figures furnished by Dr. Cressy L. Wilbur, Chief Statistician of Vital Statistics, Bureau of the Census—from Kober.)

not grow in cold water, there must have been a very considerable dilution in most of the epidemics.

The following examples are given of the fact that water-borne outbreaks of typhoid fever occur during the winter, fall, or early spring, when the water is cold. Thus we have the water-borne epidemic in Plymouth, Penn., in 1885, which began with the spring thaw and doubtless came from the frozen accumulation of typhoid excrement from a single case. Very similar to the Plymouth outbreak was that at New Haven, Conn., in 1901. The outbreak at Ithaca, N. Y., started in epidemic proportions in January. The epidemic in Sherbourne, England, in 1873, likewise started in January. Four acute epidemic exacerbations are recorded in Philadelphia in December of the years 1884, 1890, 1899, and 1903. Several similar epidemics have occurred in the winter time in Chicago—one in January, 1890, another in January, 1896, and one in March, 1891. Another striking instance is the epidemic in Newark, N. J., in February, 1899, and one in December, 1891. Abroad, epidemics are recorded in Berlin in February, 1899, in Paris in February, 1894, and in Vienna in November, 1888. All of these are generally believed to have been water-borne and must have taken place when the water was very cold. In fact, as previously pointed out, extensive water-borne epidemics of typhoid fever rarely occur in the summer time.

It was formerly thought that a high typhoid rate necessarily meant badly infected water. We know now that this does not necessarily follow, as has been proved by the experiences in Washington, Winnipeg, army camps, and many southern cities.

Almost all the water-borne epidemics of typhoid fever rest upon circumstantial evidence. It is difficult to isolate the typhoid bacillus from water, and the damage is usually done before suspicion points to the water.<sup>16</sup>

It is clear that in cities which have had safe water supplies for a period of years the typhoid death rate (residual typhoid) should not be above 5 per 100,000, unless some unusual conditions exist, such as poor control of milk, or lack of control over patients and carriers, and disregard of modern sanitary knowledge.

No single measure in reducing typhoid fever on a large scale approaches the effect of substituting a safe for a polluted water supply. As an instance of this wholesale saving of human life, the reduction of typhoid fever in four American cities is shown in Fig. 13.

**Ice.**—Ice may, under exceptional circumstances, occasionally be the vehicle by which typhoid bacilli are transferred. Freezing does not kill *B. typhosus*, but there is a great quantitative reduction not only in the

<sup>16</sup> Examples of water-borne outbreaks of typhoid fever will be found in the chapter on Water.

act of freezing, but during storage; hence the danger is greatly lessened. The only suggestive outbreak of typhoid fever attributed to ice was reported by Hutchins and Wheeler in 1903 in the St. Lawrence Hospital, three miles below Ogdensburg. A few other instances in which ice is believed to have conveyed the infection have been reported, but are based upon flimsy evidence. The fact that natural ice is usually stored many weeks or months before it is used is a sanitary safeguard. Manufactured

FIG. 12.—IMMEDIATE AND STRIKING EFFECT OF PURIFYING A BADLY INFECTED WATER SUPPLY UPON THE TYPHOID SITUATION.

ice made from distilled water and handled with cleanly methods is above reproach. For a discussion of ice in relation to typhoid fever and other infections, see page 1188 *et seq.*

**Milk.**—Trask collected 317 typhoid epidemics up to 1908 caused by infected milk. Since then many more instances have come to light. Doubtless many milk outbreaks have escaped attention or have been attributed to water or other sources. The typhoid bacillus grows well in milk, and it is now realized that this medium is a frequent and important mode of communication. Most milk outbreaks are reported

from England or America. On account of the almost universal custom of boiling the milk in European and tropical countries, milk outbreaks are rarely reported from these regions. During our four years' study of typhoid fever in Washington, it was found that at least 10 per cent. of the cases were milk-borne.

The milk usually becomes contaminated on the farm, from a case or a carrier. It may also become infected in transportation, at the city dairy, or in the home. Milk outbreaks come abruptly, rise to a peak like a water epidemic, and subside rather sharply. There are comparatively few secondary cases. Milk-borne epidemics of typhoid fever have certain characteristics which permit ready recognition.

FIG. 13.—ABRUPT REDUCTION IN DEATH RATES FROM TYPHOID FEVER INCIDENT TO WATER PURIFICATION IN FOUR AMERICAN CITIES.

Column X.—The Black Squares Indicate Raw Water and the Clear Squares Filtered Water.

(a) There is a special incidence of the disease on the track of the implicated milk supply. The disease follows the route of the milk wagon. The outbreak is localized to such areas.

(b) The better class of houses are invaded, and persons in better circumstances generally suffer most.

(c) Those who drink milk are chiefly affected and those suffer most who are large consumers of raw milk.

(d) The incidence is high among women and children.

(e) The incubation period may be shortened perhaps on account of the large amount of infection taken.

(f) More than one case occurs simultaneously in a house. This is a very suspicious circumstance to the epidemiologists. The first indication of a milk outbreak in a city with a good water supply is usually the fact

that two or more persons in a household come down with typhoid fever within a few days of each other.

(g) Clinically the disease often runs a mild course, owing to the fact, no doubt, that the virus becomes attenuated in the process of multiplication in the milk. In water-borne typhoid the same germs are ingested that were passed; in milk-borne typhoid it may be the succeeding generations that are ingested.

Milk-borne outbreaks are sometimes very extensive. One of the largest epidemics occurred in Boston (Jamaica Plain) in March and April, 1908. Four hundred and ten cases were reported; 348 of them drank the suspected milk. Among the first victims of the disease was the milkman, who was believed to have infected the milk through tasting it. The number of persons involved in a milk-borne epidemic varies greatly, depending upon the amount of milk infected and other factors. It must not be uncommon for a single bottle of milk or a small quantity to become infected, and thus transmit the disease to one or two persons. Such instances are exceedingly difficult to trace. Ofttimes the milk becomes infected from a carrier. An instance of this occurred in Washington (Georgetown) in 1908. In this case the milkmaid had typhoid fever 18 years previously. Examinations showed almost pure culture of *B. typhosus* in her feces. Fifty-five persons who drank the infected milk contracted the disease.

**Milk Products.**—Fresh milk products, such as cream, ice cream, butter, and buttermilk, and fresh cheese, may contain the typhoid bacillus, and are occasionally media of communication.

*Cream* contains more bacteria than the milk from which it is taken. The use of infected cream in coffee, on cereals, etc., is sufficient to cause the disease. Several instances in the Washington studies were traced to such use of cream. As a rule, coffee in the cup is not hot enough to kill the typhoid bacillus, if present in the cream added.

In Washington several cases of the disease were traced to ice cream. Mitchell working in my laboratory found that *B. typhosus* survives in ice cream for from 12 to 39 days. Lumsden<sup>17</sup> traced the Birmingham, Alabama, outbreak in 1916, and another in Chattanooga, Tennessee, in 1917, to ice cream. An outbreak at Helm, California, in 1916, was found by Cumming to be due to ice cream.<sup>18</sup>

Bruck has shown that the typhoid bacillus will live in butter for 27 days.

*Buttermilk* may be quite as dangerous as the cream from which it is derived. The acidity and overgrowth of other organisms is said to kill the typhoid bacillus in 24 hours. In *cheese* the time of fermentation, antibiosis, etc., lessens the likelihood of survival of the

<sup>17</sup> *Am. Jour. Public Health*, December, 1917.

<sup>18</sup> *J. A. M. A.*, April 21, 1917, LXVIII, 16.

typhoid bacillus. Fresh cream cheese, such as cottage cheese, may be responsible for an occasional case.

**Oysters, Mussels, and Shellfish.**—The first outbreak of typhoid fever attributed to this source was investigated by Conn at Wesleyan University, Middletown, October, 1894. Twenty-five cases were attributed to eating infected oysters; 4 died. Not all of those who took sick had clinical typhoid fever. Some had gastro-intestinal disturbances with illness lasting but a few days. About one-quarter of those attending the dinners at which the oysters were served were made ill.

A similar instance occurred at the Mayors' banquets at South Hampton and Winchester, in 1903.

Dr. L. W. Darra Mair<sup>19</sup> showed that much of the typhoid fever in Belfast, Ireland, from 1897 to 1901, was due to eating cockles and mussels taken from sewage polluted water. The amount of the fever diminished markedly and its seasonal prevalence was changed by betterment of the shellfish situation.

In Brighton, England, Dr. J. T. C. Nash<sup>20</sup> proved that much of the typhoid fever in the Borough of Southhead-on-Sea prior to 1899 was due to infected oysters. There was a sharp reduction in the amount of fever when the fore shore fisheries were stopped, and almost a cessation of all cases when attention was given to all shellfish, including the improved laying and cooking of cockles.

In the Washington studies it seems that oysters and shellfish play a minor rôle in the spread of the disease, which occurs mostly in the summer time, while oysters and similar sea food are relished mainly in winter. Comparatively few of the cases studied gave a history of having eaten oysters within 30 days prior to the onset of the disease. Oysters become dangerous when consumed soon after taking them from a polluted bed, or when floated or bloated in infected water. For further discussion of this topic, see page 840.

**Fruits and Vegetables.**—Vegetables, such as celery, lettuce, water cress, and radishes, partaken raw, and grown on land fertilized with fresh night soil, may be infected, and this probably accounts for an occasional case.<sup>21</sup> Vegetables so contaminated are not made safe by the ordinary methods used in preparation of such food for table use. In large cities it is practically impossible to trace this source of infection. It therefore remains more a suspicion than a conviction. An outbreak which occurred in the summer of 1905, in Springfield, Mass., was attributed to infected fruits and vegetables.

At a wedding breakfast in Philadelphia June 24th, with 43 guests in

<sup>19</sup> Proc. Roy. Soc., Epidemiology Sec., April, 1909, Vol. II, Part 2.

<sup>20</sup> *Idem*.

<sup>21</sup> Melick, J., Infets. Dis., Vol. XXI, No. 1, July, 1917, p. 38.

attendance, 19 persons ate watercress sandwiches.<sup>22</sup> Eighteen of these were ill July 22nd with typhoid fever, only 2 of them being in Philadelphia at the time, while the other 16 were scattered in suburban territory and in summer resorts along the Atlantic Coast as far north as Maine. The watercress had been secured from a farm on which the sanitary conditions were quite unsatisfactory. A similar outbreak occurred in Hackney, London, in 1903, although the evidence in that outbreak was not so convincing. Morse<sup>23</sup> reports an outbreak presumably due to celery.

Creel<sup>24</sup> found typhoid bacilli upon the tips of leaves of plants cultivated in contaminated soil. Under conditions most unfavorable to the *B. typhosus* the infection lasted at least 31 days—a period sufficiently long for some varieties of lettuce and radishes to mature.

Vegetable salads are sometimes accused of conveying typhoid and other infections, but in these instances it is more apt to be the salad dressing than the salad itself. See an outbreak reported by Leake due to mayonnaise dressing prepared by a person in the early stage of the disease.<sup>25</sup>

**Flies.**—The evidence is now complete that the common house fly (*Musca domestica*) may convey the infection of typhoid. It is not inappropriately called the typhoid fly. The typhoid bacilli may be smeared upon the feet or other parts of the insect, or may live in the intestinal tract and pass in the dejecta in almost pure culture. Flies live, feed, and breed in fecal matter and decomposing organic substances of all kinds. It is easy to see how they may convey infections from this source to our food, lips, or fingers. Alice Hamilton isolated typhoid bacilli from 5 out of 18 house flies captured in Chicago in the privy and on a fence near a sick room during a local water-borne epidemic. It has been shown experimentally that living typhoid bacilli may remain upon the bodies of flies for as long as 23 days. Special attention to the rôle played by the fly was given by Reed, Vaughan, and Shakespeare in their studies of the prevalence of typhoid fever in our army camps in 1898. They concluded that flies undoubtedly served as carriers of the infection and attributed about 15 per cent. of the cases to this mode of communication. They found that “flies swarm over infected fecal matter in the pits and then deposit it and feed upon the food prepared for the soldiers at the mess tents. In some instances, where lime had recently been sprinkled over the contents of the pits, flies with their feet whitened with lime were seen walking over the food.” The danger from fly transmission varies very much, and depends upon circumstances. In a camp it is considerable; in a well sewered city the risk is diminished. In our

<sup>25</sup> *Public Health Reports*, Sept. 17, 1920, Vol. XXXV, No. 38, p. 2197.

Washington studies we could find no relation between fly abundance in the summer of 1908 and typhoid prevalence. It is not possible to express mathematically the percentage of cases caused by flies—the figures would vary greatly, depending upon circumstances. The danger of typhoid from flies in cities has doubtless been overstated. However, if only one per cent. of the cases were thus transmitted, the suppression of flies would still be quite worth while (page 312).

**Dust.**—Typhoid bacilli soon die when dried, especially when exposed to the sun and air. Dust-borne infection in this disease must be rare. In the South African War there were frequent dust storms in some localities, so that the food was covered with dust and sand. Some of the infection was believed to have been conveyed in this way.

**Fomites.**—The infection may be conveyed upon soiled linen, blankets, and other objects. It was believed by Reed, Vaughan, and Shakespeare that the clothing, blankets, and tents in the Spanish-American War became infected and were a prime factor in spreading the disease. After the South African War some of the blankets used by the troops were sent back to England and used on a training ship, on which typhoid fever appeared. The blankets were found to be dirty and soiled with fecal matter, from which Klein is reported to have obtained living typhoid bacilli. The danger of fomites contaminated with fresh infection is real, and emphasizes the importance of disinfecting bedding, towels, handkerchiefs, body linen, and other fabrics.

**Soil.**—The soil, long regarded as the most important factor in the spread of typhoid fever, and by Pettenkofer and others considered an essential element, is now given scant consideration. Pollution of the soil, however, cannot be disregarded. The typhoid bacillus may live for a long time in sewage-soaked earth. A polluted soil may endanger the water, milk, and other foods, or infect indirectly through flies and other means. For more extended information on this subject, see Section VII.

**Contact Infection.**—"Contact" is a convenient term to indicate the spread of infection directly or indirectly as a result of close association between the sick and the sound. Actual contact is not necessarily implied. The term is used to indicate the transfer of the infection through a short intervening space in a brief period of time (see page 461). Thus the infection may be passed from one to another through kissing, soiled hands, remnants of food, infected thermometers, or tongue depressors, contaminated towels or other fabrics; cups, spoons, glasses, etc. If the nurse infects a cup of milk or glass of water that carries the infection to another member of the household, such cases are included under "contacts." The infection may also be spread in the household by flies, fingers, and various other means, usually difficult to trace, and which are, therefore, all included under this group. Regarded in this light, contacts play a large rôle in the spread of the disease.

Extensive municipal outbreaks have been reported as largely or entirely due to contact infection. Winslow in 1901 studied such an outbreak in Newport. Others have been reported from Knoxville, Winnipeg, Springfield, and from Germany and England. Koch regarded the spread of typhoid in Trier in the light of contact infection. Freeman says that the majority of outbreaks in the smaller towns of Virginia are due to this cause. Extensive outbreaks in institutions are often due to contact with mild cases or carriers. "Flies, fingers, and food" (Sedgwick), and "dirt, diarrhea, and dinner" (Chapin), which too often get sadly confused, explain the occurrence of many a case of contact infection in typhoid fever as well as other diseases.

In army camps with clean water and good milk, contact infection may rise to epidemic proportions. In the Spanish-American War, of 107,361 of our troops in camp, 20,738 contracted typhoid, mostly by "contact"; 1,580 died. Similar conditions prevail in rapidly growing cities, in crowded apartments, and in congested regions with a susceptible population and other favoring conditions. The danger of contact is well shown by the frequency with which nurses, ward attendants, house physicians, and others similarly exposed take typhoid fever. Studies of the incidence of the disease in the Massachusetts General Hospital, Boston, in the Presbyterian Hospital, Philadelphia, and in the Johns Hopkins Hospital, Baltimore, show that typhoid fever was at least twice and may be eight times as prevalent among those who came in close and frequent association with the patient as among the population at large. Further, the disease contracted under such conditions seems to run a course of more than ordinary severity, with a greater number of complications and with a high mortality. This is doubtless due largely to the fact that the contactors receive fresh virulent virus.

In our studies of typhoid fever in Washington we were impressed with the importance and frequency of contact infection in that endemic center. In 1907 we attributed 6 per cent. of the cases to contacts; in 1908, 15 per cent., and in 1909, 17 per cent. This included only contact with cases during the febrile stage of the disease. In Strassburg, Kayser attributed 16.8 per cent. of the cases occurring during 3 years in that city to contact infection. Little groups of cases following a primary case in a suburban focus, in my experience, frequently fall in the category of contacts.

Typhoid fever, in view of all the facts, must now be regarded as a "contagious" disease. We will never have an end of it until it is so regarded and managed accordingly.

## TYPHOID VACCINES

**Preventive Typhoid Inoculations.**—An active immunity to typhoid fever may be induced by introducing dead typhoid bacilli into the subcutaneous tissue. The procedure is *harmless, rational, and effective*.

Our knowledge of inoculations against typhoid fever began with the work of Pfeiffer and Kolle,<sup>26</sup> who inoculated two volunteers in 1896. About the same time Almroth Wright<sup>27</sup> inoculated several persons, and in 1898 continued the work upon an extensive scale in India upon 4,000 British soldiers. In 1900, during the Boer War, Wright, together with Leishman, prepared a vaccine<sup>28</sup> and supervised the inoculation of 100,000 British troops. The results in India were quite encouraging, but for various reasons the same procedure in South Africa was not as satisfactory as had been anticipated. Prophylactic inoculation on the advice of Koch was used by the Germans in the Herero campaign in southern West Africa in 1904. The prophylactic was voluntary and only about half of the command (7,287 men) availed themselves of it. The results, while good, fell short of expectations. In this country Richardson was the first to advocate and practice inoculations as a means of protection against typhoid fever. The best results have been obtained in the United States Army where typhoid inoculations were recommended as a voluntary protection in 1909, but were made compulsory in 1911.

Leishman<sup>29</sup> in his Harben lecture (1910) explains the lack of success in early years by saying that the vaccine may have been made less efficient by the use of too great heat in killing the bacilli. Further, it should be noted that smaller doses and fewer injections were given then than now. It is well to know that it took about ten years to establish the efficiency of typhoid prophylactic inoculations.

The typhoid vaccines may be prepared in a number of different ways. Usually dead bacilli are used, although live bacilli have been inoculated. The bacilli may be killed either with the aid of heat or germicidal substances; the dead or live bacilli may be sensitized by the addition of anti-typhoid serum; the vaccines may be prepared with pulverized bacilli, from bacillary extracts, or by the use of various chemical methods.

Lipovaccines are made by suspending the bacilli in a fluid fatty substance of suitable consistency. The vegetable oils are better for this purpose than the animal fats. Lipovaccines are absorbed slowly and therefore the entire amount can be inoculated at one time. Experi-

<sup>26</sup> Pfeiffer and Kolle: *Deutsche med. Wochnschr.*, 1896, XXII, 735.

<sup>27</sup> Wright: *Lancet*, London, Sept. 19, 1896, 807; *Brit. Med. Jour.*, Jan. 30, 1897, 16.

<sup>28</sup> The material injected is called a vaccine and the process is spoken of as vaccination. The term in this connection is a little confusing.

<sup>29</sup> Leishman, W. B.: *Jour. Roy. Inst. Pub. Health*, London, 1910, XVIII, 394.

ments indicate that lipovaccines have only about one-half the protective power of saline suspensions. See Lipovaccines, page 536.

Usually the vaccine is made from a twenty-four-hour-old culture killed by heating to 53° C. for thirty minutes, depending upon phenol (0.5 per cent.) to kill any bacilli that may have survived. Overheating impairs the immunizing power of the vaccine. Most typhoid bacilli die before the temperature reaches 60° C. Some of the strains have a lower thermal death point. Cultures killed without heat have perhaps greater protective properties. The killed cultures are suspended in saline solution,—isotonic salt solution.

Certain strains seem to cause the production of more antibodies than others. In the earlier work it was believed that the more virulent strains produce a greater protection. This is doubtful, for it appears that the protection afforded is not in proportion to the local or febrile reaction, but to the amount and variety of antibodies stimulated. The Rawlins strain is now greatly used in this country for experience has proved its protective power.

The injections are given subcutaneously at intervals of from five to ten days. From 500,000,000 to 1,000,000,000 dead typhoid bacilli are injected at each inoculation. The number of inoculations varies with different authorities. At least 3, preferably 4, should be given; the greater the number of injections the greater the immunity induced.

The reactions are usually moderate and never serious. They consist of local manifestations; irritation, and inflammation about the site of inoculation, such as pain, redness, swelling, edema; also general symptoms, such as malaise, pains in the back and limbs, and fever. The number and character of the reactions in the experience of the United States Army<sup>30</sup> are shown in the following table:

	Number of doses	Reaction, Absent	Reaction, Mild	Reaction, Moderate	Reaction, Severe
First dose.....	45,680	68.2%	28.9%	2.4%	0.3%
Second dose.....	44,321	71.3%	25.7%	2.6%	0.2%
Third dose.....	38,902	78.0%	20.3%	1.5%	0.1%

Children, as a rule, react less than adults. Of 1,101 persons inoculated by Hartsock, 11 per cent. showed no reaction, 83 per cent. mild reaction, 5 per cent. a moderate reaction, and 1 per cent. a severe reaction. There is always some local tenderness and redness at the point of inoculation. The systemic symptoms usually pass in 24 hours.

The best time to give the treatment is late in the afternoon, for then the severest part of the reaction is over by the morning. The injections

<sup>30</sup> Russell, F. F.: *Jour. A. M. A.*, LVIII, No. 18, May 4, 1912.

are usually given into the subcutaneous tissue of the outer side of the arm or into the abdominal wall; sometimes the interscapular space.

There is no laboratory index of the degree or duration of the immunity produced as a result of the inoculations. The following antibodies appear in the blood: agglutinins, precipitins, opsonins, lysins, stimulins; agglutinins persist for 2 years and even longer. There are factors involved in the immunity not understood, and therefore, the subsequent freedom of typhoid fever among individuals protected in this manner is the only index of value.

The negative phase advanced by Wright and denied by Leishman and others does not occur. At least there appears to be no increased susceptibility to the disease during the so-called negative phase. There is, therefore, no known objection to giving the prophylactic to those exposed to the disease or during an epidemic. In fact, the typhoid vaccines have been used as a therapeutic agent during the fever.

The immunity varies in degree and also in duration; at least one year (Pfeiffer and Kolle's vaccine); four years (Wright's vaccine). On the average, the immunity may probably be depended upon for about 3 years when produced by 4 injections of dead bacilli.

In the United States Army typhoid immunization is repeated every three years. In case, however, two or more cases occur in the same command within two weeks, then the entire command is again inoculated. The experience of the American Expeditionary Forces showed that the immunity is not sufficiently strong or durable to protect against mass infections. The immunity may be prolonged or renewed by recourse to reinoculation.

One attack of typhoid fever, however mild, produces, as a rule, a lasting immunity. Second attacks, however, occur. Draschfeld's figures, based on 2,000 persons in the Antwerp Hospital, show that only 0.7 per cent. of that number were affected twice. This percentage is doubtless too high, for the figures were collected before our knowledge of paratyphoid infections. The typhoid vaccines do not protect against paratyphoid infections, and contrariwise paratyphoid does not protect against typhoid.

In the United States Army, where the vaccinations are done under the supervision of Major Russell, we have the following results:

During 1913 the army had only two cases of typhoid in the enlisted force of over 80,000 men. One of these occurred in a man who had not been vaccinated; the other was among the troops in China, who had been immunized in 1911 and the history of the case is in doubt. In six years, 1909 to 1914, there was only one death from typhoid in the U. S. Army, while the rate in the country at large averaged over 16.5 per hundred thousand.

The health record established by the Maneuver Division of the

\* Typhoid vaccination was voluntary during 1909 and 1910, and until Sept. 30, 1911, when it was made compulsory for officers and men.

United States Army at San Antonio, Texas, during the summer of 1911, is a triumph in preventive medicine. The division had a mean strength of 12,801 men. All were treated with the typhoid vaccines. The result was that from March 10th to July 10th only two cases of typhoid fever developed; no deaths. One patient was a private of the hospital corps who had not completed his immunization, having taken only two doses. His case was very mild and probably would have been overlooked but for the rule that blood cultures were made in all cases of fever of over 48 hours' duration. The other case was a teamster who had not been inoculated. Among the 12,801 men there were only 11 deaths from all diseases. Typhoid fever prevailed at the time in the neighborhood. Thus, there were 49 cases of typhoid fever with 19 deaths in the city of San Antonio during this period. This contrasts markedly with the typhoid record of the United States Army during the Spanish-American War, when the typhoid record of a division of volunteer troops camped at Jacksonville, Florida, in 1898, under conditions similar to those at San Antonio, was as follows: The division at Jacksonville had 2,693 cases with 248 deaths, which was about the average typhoid incidence of the camps.

The U. S. Navy had only seven cases among 50,000 men during the year ending June, 1913. Four of these occurred among men treated at a tropical station, where the vaccine had deteriorated. All the cases were mild. The results in recent years are still better. By contrast, in 1911 the rate was 3.61 per 1,000.

Spooner reports that in the Massachusetts General Hospital,<sup>31</sup> among the nurses and others exposed to typhoid fever, 80 per cent. of whom had been inoculated during the previous three years, not a case was contracted, and for the first year in the history of the institution (1912) there were no cases among the nurses or attendants. The morbidity rate in training schools for nurses in Massachusetts during three years was nearly nine times greater in the uninoculated than among the inoculated.

Metchnikoff and Besredka<sup>32</sup> failed to protect chimpanzees against typhoid infection by means of killed bacilli, but obtained immunity apparently as definite as that produced by an attack of the disease by the use of living cultures.<sup>33</sup>

*Polyvalent Vaccines.*—It is now customary to use a vaccine consisting of a mixture of *B. typhosus*, *B. paratyphosus a*, and *B. paratyphosus β* as a routine, because the typhoid vaccines do not protect against paratyphoid infections, and vice versa. During the World War, it was customary to add other cultures such as cholera, dysentery or plague to the mixture for troops serving in localities where these infections prevailed. These various mixtures apparently produce no greater reaction than the single typhoid vaccine and induce a specific active immunity against each virus represented in the mixture. Dose and number of injections remain approximately the same as for single vaccines.

*Summary.*—The results of typhoid inoculations can no longer be questioned. The morbidity is lowered in those who have been properly "vaccinated." The most striking effect is in the lowering of the mortality. Preventive typhoid inoculations involve no risk whatever, and are especially applicable to those unduly exposed to the infection, such as nurses, hospital attendants, physicians, travelers, soldiers in camps, persons in epidemic localities, and individuals in the family of a bacillus carrier. Typhoid vaccination should be mandatory in asylums and other custodial institutions. The method is serviceable for general use among the public in endemic foci, but it is a question whether this artificial method of acquiring immunity would serve as good a purpose in the end as fighting the disease along the lines of general sanitation—which has been so successfully done in many European centers. It would certainly be a mistake to immunize the population with this artificial method to the neglect of general sanitary improvements, such as good water, clean milk, fly suppression, cleanliness, and personal hygiene. Because a person has received the protection afforded by typhoid inoculations is no reason for reckless disregard of other prophylactic measures. The experience of the American Expeditionary Forces showed that vac-

<sup>31</sup> Transactions of the Assn. of Amer. Physicians, 1912.

<sup>32</sup> *Ann. de l'Inst. Pasteur*, Dec., 1911, XXV, 12, p. 865.

<sup>33</sup> *Ann. de l'Inst. Pasteur*, Mar. 25, 1911, and Dec., 1911.

cination is a partial protection only, and that *typhoid vaccination is no substitute for sanitary precautions*.

Typhoid vaccination can be used to help suppress a typhoid epidemic.

**Management of a Case so as to Prevent Spread.**—Success depends upon an early and accurate diagnosis. All cases of typhoid fever and all cases suspected of being typhoid fever should be isolated. This does not mean imprisonment in a lazaretto. The proper place to care for typhoid fever is in a suitable hospital. A private home is a poor makeshift for a hospital, and it is unreasonable to turn a household into a hospital for 4 to 8 weeks or longer. The room in which the patient is treated should be large and well ventilated, and should contain no unnecessary furniture, curtains, carpets, etc. It must be well screened and kept scrupulously clean, dry sweeping and dusting prohibited.

The case should be reported to the health authorities without delay; the house should be placarded so as to warn others, and visiting discouraged. Under no circumstances should visitors be admitted into the sick room.

The health officer should send an epidemiologist or a public health nurse without delay to the premises to instruct and to see that all necessary measures are being taken.

The disinfection of the stools, urine, sputum, and other excretions is of the first importance, and should be carried out with great care and conscientiousness. For the urine, sufficient bichlorid may be added to make a 1-1,000 solution, or carbolic, 2.5 per cent., or formalin, 10 per cent., and allowed to stand one hour before discarding. Stools may be disinfected with bleaching powder, 3 per cent.; milk of lime (1 to 8); cresol, 1 per cent.; carbolic acid, 5 per cent.; formalin, 10 per cent.; or unslacked lime and hot water (page 1432). The discharges should be received in a glass or earthenware vessel containing some of the germicidal solution. Then add more of the solution so that it shall be present in twice the volume of the excreta to be disinfected; disintegrate the masses thoroughly and let stand at least two hours, protected from flies. Masses are so difficult to penetrate that they must be broken up thoroughly with a wooden paddle. It takes a strong carbolic solution 12 hours to penetrate the interior of a small fecal mass; larger masses are impenetrable to most germicides.

The sputum may be burned or boiled. Strong carbolic acid, cresol, or formalin are also applicable.

The patient should have his own dishes, cups, spoons, glasses, etc., which should be scalded after each use. Remnants of lunch, especially meat, milk, gelatin, broths, and other organic food in which the infection may live and even grow, should not be eaten by others. Such remnants may be burned or first boiled and then discarded. Those who nurse the

sick should keep out of the kitchen on account of the risk of contaminating the food.

Handkerchiefs, towels, sheets, nightgowns, and all fabrics used about the patient should be disinfected either by boiling, or by immersion for one hour in bichlorid of mercury, 1-1,000, carbolic acid, 2.5 per cent., or cresol, 1 per cent.

The water used to bathe the patient should be disinfected before it is allowed to run into the sewer. This may be done by heat or by adding sufficient carbolic acid or bleaching powder; the latter is cheapest and most practical.

Milk bottles must be kept out of the sick room. In any case, they should be scalded before leaving the house and again disinfected before returning to the dairy.

The thermometer should be kept in formalin, alcohol or other suitable germicidal solution. Rectal tubes, especially in hospital practice, must be carefully disinfected each time before using. Individual instruments are preferable.

The nurse must protect herself as well as others; a solution of bichlorid should be kept constantly at hand. Every time the patient is bathed, his mouth cleaned, or his buttocks washed, the hands must be washed in soap and water and disinfected. The nurse must exercise especial care if she is to go to the kitchen or to the ice-box, etc., as is frequently the case in private houses, where a special diet kitchen cannot be provided. The nurses, physicians, ward attendants, and others particularly exposed should protect themselves with preventive typhoid inoculations. The physician should be quite as careful as the nurse, not only that he may not carry the infection to himself or other patients, but also that his practice may serve as a stimulating example.

At the conclusion of the case a general cleansing and disinfection of the room and its contents should be practiced.

Convalescents should not be given liberty until the danger of bacillus carrying has passed. A large percentage of patients continue to eliminate typhoid bacilli during convalescence. This may be determined only by bacteriologic examinations of the stools and urine. Four successive negative results at intervals of several days are required before a report may be vouchsafed in the case of the stools. In the case of a chronic bacillus carrier, the failure to find typhoid bacilli in the stools is no assurance of cure. In Sawyer's case frequent examinations extending over a period of 4 months proved negative, yet the carrier subsequently infected 3 persons. One examination of the urine is ordinarily sufficient.

The use of hexamethylenamin during the fever diminishes the incidence of bacilluria, and should be a routine practice.

Finally, every case of typhoid fever should be painstakingly traced

to its source. In this way, carriers and other foci will be detected and much further harm prevented.

**Summary—Personal Prophylaxis.**—The prevention of typhoid fever may be summed up in the word cleanliness—physical and biological cleanliness. By this is meant not only clean food, especially water and milk, but also cleanliness of person and environment. Typhoid fever has always prevailed where cleanliness is neglected and has diminished where it has been intelligently observed. It is true that typhoid bacilli do not breed in the rubbish and dirt of back yards and alleys, or in unkempt city lots, but these conditions in a community may be taken as an index of the general cleanliness of its inhabitants.

The eradication of typhoid fever is easier in cities than in country districts; clean cities now have less typhoid fever than the surrounding rural regions. Cities can well afford extensive and expensive sanitary works which are beyond the financial possibilities of sparsely settled districts. If a clean water from natural sources is not available, then large volumes of a polluted water may be rendered reasonably safe for municipal use by slow sand filtration and by bleaching powder. Further, cities can afford to inspect their milk supply and to supervise the pasteurization of all that is not safe. These two measures would practically eliminate typhoid infection coming into cities in its food supply—especially if in addition to this a supervision is maintained over oysters and shellfish, and vegetables partaken in their raw state. Further, cities can well afford to employ skilled and experienced health officials and are financially able to engage the services of experts. On the other hand, each farmhouse represents, in miniature, all the problems with which the city deals by wholesale, and is often not financially able to meet its sanitary requirements. The country is the weakest link in our sanitary chain. The good results obtained in the rural region of Yakima, Washington, and in several counties of Maryland by Lumsden, through intelligent and intensive measures, are a great object lesson in rural sanitation.

Cities will find it a paying proposition to suppress flies, rats, and other vermin, which may be done much more easily than under rural or suburban conditions. This should be done not only on account of the suppression of typhoid fever, but other diseases thus conveyed. The city beautiful must also be the city clean,—clean in its cellars, garrets, back yards, empty lots, alleys, and stables.

To sum up, the main factors in the spread of typhoid fever in our large cities are: (1) water; (2) milk; (3) contact; (4) miscellaneous. In a city having a clean water supply the residual typhoid must be attacked along two definite lines, viz., improvement of the milk supply and its pasteurization, and a warfare against the disease in the light of an infection spread from man to man.

The health officer should establish a laboratory for the early diagnosis

of cases and for the discovery of carriers. The health officer should at once send a trained agent to every house from which a case of typhoid fever is reported. The visit should be made as early as practicable and with the object of seeing that the stools and urine are properly disinfected, patients isolated, milk bottles scalded, sick rooms screened, house placarded, visiting discouraged, and other necessary measures taken to prevent the spread of the infection. *Each case should be traced so as to prevent further harm from the same source.* Convalescents should not be released until the absence of typhoid bacilli from the urine and stools has been demonstrated by at least four successive examinations. Carriers need not be indefinitely quarantined, but should be prohibited from engaging in any employment having to do with foods, or in which close personal contact, as in nursing, is required. Carriers should be instructed concerning the danger and educated to wash and disinfect their hands thoroughly, especially after a visit to the toilet.

The health officer alone cannot eliminate typhoid fever from a city. He needs the help of the community. Much can be done through education. A stimulating leader may accomplish a world of good through voluntary effort, but in the end it requires comprehensive laws and an energetic enforcement of them, without fear or favor.

The personal prevention of typhoid fever resolves itself into boiling the water, if suspicious; partaking only of milk or fresh milk products that have been pasteurized, and otherwise assuring oneself that all food has been thoroughly cooked. In addition to this, direct and indirect contact with persons who have the disease, or who are known to be carriers, must be avoided. Sanitary habits should be encouraged, especially the one simple precaution of washing the hands after defecation and before eating, and of keeping the fingers and other unnecessary objects away from the mouth and nose. Finally the protection afforded through typhoid inoculations may be used.

### PARATYPHOID FEVER

Paratyphoid fever both clinically and etiologically is a first cousin of typhoid fever. The two diseases are indistinguishable at the bedside. It needs the aid of the laboratory to differentiate one from the other. The epidemiology of paratyphoid fever shows marked differences from that of typhoid fever.

Paratyphoid is a world-wide infection; outbreaks occur, but, as a rule, are of limited extent. Paratyphoid never occurs as great epidemic calamities, such as have been frequently observed in water-borne or milk-borne typhoid. Paratyphoid coexists with typhoid in endemic foci. Thus, in Washington somewhat over 1 per cent. of all the cases

reported as typhoid fever were shown, upon bacteriological examination, to have been paratyphoid. In India the proportion is greater, being as high as 15 per cent. In many localities, about 10 per cent. of typhoid fever is in reality paratyphoid fever.

In 1896 Acharde and Bensaude isolated from the urine of a case of apparent enteric fever, and also from a purulent arthritis, following a similar illness, a bacillus which they called the "paratyphoid bacillus." In 1900-01 Schottmüller obtained from the blood of patients whose symptoms were those of enteric fever two bacilli resembling the paratyphoid bacillus of Acharde and Bensaude. These two organisms were later named by Brion and Kaiser "*paratyphosus*  $\alpha$ " and "*paratyphosus*  $\beta$ ." Paratyphoid  $\beta$  is much more common and widespread than paratyphoid  $\alpha$ .

The paratyphoid bacillus is a small rod with rounded ends and peritrichal flagellae resembling the typhoid bacillus. It stains readily with anilin dyes, is decolorized by Gram's method, does not liquefy gelatin, has no spore, and is a facultative aërobe; it clouds bouillon uniformly, and does not produce indol. Upon Endo's medium the paratyphoid colonies are pale, moist, translucent, with a bluish cast, quite similar to typhoid colonies.

The paratyphoid bacillus ferments dextrose, mannite and maltose with the production of gas—whereas the typhoid bacillus produces no gas. They also vary greatly in pathogenicity for the lower animals. Typhoid cultures, as a rule, are not very pathogenic for the lower animals,<sup>34</sup> whereas guinea-pigs and mice are susceptible to paratyphoid cultures; most strains will kill guinea-pigs when 1/50 to 1/100 of a loop is injected into the peritoneal cavity. Rabbits are also susceptible; birds are entirely refractory; cattle, dogs, cats, hogs, and sheep, show a high degree of resistance to paratyphoid cultures.

A fundamental point of difference between the paratyphoid and the typhoid organisms is that each has specific agglutinating properties. This difference and gas formation in certain sugars are the most important distinguishing features. Care must be taken, in using agglutinins, in differentiating these closely allied species, to guard against confusion through group agglutinins, and also to keep the pro-agglutinated zone in mind.

The paratyphoid bacillus may be found in the blood and internal organs, also in the feces; seldom in the urine. It produces a continued fever in man closely resembling typhoid fever. As a rule, paratyphoid is milder than typhoid. Lentz<sup>35</sup> gives a mortality of 3.3 per cent. against typhoid, which is about 9 per cent.

<sup>34</sup> Cultures injected into animals do not produce fevers clinically similar to typhoid or paratyphoid fevers.

<sup>35</sup> Centralblatt. f. Bakt., Referate, Bd. XXXVIII.

Paratyphoid fever may be complicated with hemorrhages from the bowels, bronchitis, and pneumonic processes, just as in typhoid fever; relapses are rare. It is not definitely known how much of an immunity is conferred by one attack, but it is known that paratyphoid fever does not protect against typhoid fever nor does typhoid protect against paratyphoid. The prophylactic power of each bacterial vaccine is also specific; that is, typhoid vaccine does not protect against paratyphoid fever, and vice versa.

Paratyphoid outbreaks have resulted from infected water, milk, and other food. The outbreaks are usually limited in number and extent. Contact infection occurs, and carriers spread the disease. Prevention is a counterpart of that for typhoid fever.

**Paratyphoid Fever and Food Poisoning.**—*B. paratyphosus*  $\beta$  is closely related to the bacillus of hog cholera (*B. suispestifer*) and to Gaertner's bacillus (*B. enteritidis*); in fact, these three bacilli are very close kin. In the German literature, *B. suispestifer* and *B. paratyphosus*  $\beta$  are considered to be identical. Differences, however, have been clearly established by the extended use of cultural, agglutination and absorption tests, especially by the English investigators Bainbridge and Savage, and by the American bacteriologist Weiss and also Krumwiede.

Food poisoning is commonly due to the *Bacillus enteritidis* of Gaertner, or *B. suispestifer* (see page 696). Some investigators still include *B. paratyphosus*  $\beta$ , and these cases were formerly called meat poisoning. Conradi and Rommeler believe that food infection may be caused by the paratyphoid bacillus and think that under these circumstances the food usually becomes infected from human carriers.

In most outbreaks of food infection, the cases are acute, with the ordinary symptoms of gastro-intestinal irritation,—nausea, vomiting, cramps and diarrhea,—but a few protracted cases of febrile infection are met with.

There is evidence in the very interesting outbreak recorded by Bainbridge and Duffield (1911), that *B. paratyphosus*  $\beta$  can cause acute gastro-enteritis, simulating food poisoning. This occurrence, however, was probably not due to a common food supply and the infection is believed to have come from a carrier.

Savage insists that no food poisoning outbreaks have been shown to be due to *B. paratyphosus*  $\beta$ , but that all are due to *B. suispestifer* or *B. enteritidis*, with possibly a few closely allied forms. Human carriers of *B. suispestifer* and *B. enteritidis* are rare. There is still much work to be done before these closely allied organisms are finally classified.

For further discussion of this subject, see Food Poisoning, page 692.

## CHOLERA

The prevention of cholera corresponds to the prevention of typhoid fever. In the case of cholera, vigorous measures have been rewarded with signal success. It is quite possible to live in the midst of a raging cholera epidemic without contracting the disease. Within recent years epidemics have been suppressed and the spread of the infection limited.

The home of true cholera is the delta of the Ganges, hence it is usually called "Asiatic cholera" to distinguish it from *Cholera nostras* or *Cholera morbus*. During the sixteenth, seventeenth, and eighteenth centuries cholera was epidemic at various times in India. It is estimated that 4,000,000 died of cholera in India from 1902 to 1911. It is only in the nineteenth century that cholera has spread along the routes of trade and travel to Europe (first in 1830); Africa, and America in 1832. There have been four pandemics; one from 1817 to 1823, another 1826 to 1837, a third 1846 to 1862, and a fourth from 1864 to 1875. In 1832 it entered the United States by way of New York and Quebec and reached as far west as the military posts of the upper Mississippi. The disease recurred in 1835 and 1836. In 1848 it entered the country through New Orleans and spread widely up the Mississippi and was dragged across the continent by the searchers for gold all the way to California (1849). It again prevailed widely through this country in 1854, having been introduced by immigrant ships into New York. In 1866 and 1867 there were less extensive epidemics. In 1873 it again appeared in the United States, but did not prevail widely. Since then, only occasional cases at seaports have occurred. In 1892 the great epidemic of Hamburg occurred, and the disease threatened to become pandemic in Asia, Africa, and Europe. Cases were brought by transatlantic liners to New York, and a few cases occurred in the city, but its spread was prevented by aggressive measures. Cholera has prevailed for years in the Philippines, but is now under control. While the home of cholera is in the tropics, there is scarcely a country in the world that has not been visited some time or other by the ravages of this fatal disease.

The incubation period of cholera is short, frequently 1 or 2 days, rarely over 5. The period of detention in quarantine is 5 days. One attack produces a mild grade of immunity which is not lasting. The disease is peculiar to man.

**The Cause and Contributing Causes of Cholera.**—The *Vibrio cholerae* or the "comma bacillus" discovered by Koch in 1883 is the undisputed cause of the disease.<sup>36</sup> The conditions of infection, however, are com-

<sup>36</sup> Choleraic symptoms may be induced by other organisms, or by certain poisons. These cases, known as *cholera nostras* or *cholera morbus*, are becoming increasingly rare. Winter cholera is the name of a mild diarrheal disease in this country. It is of unknown etiology, but has nothing to do with true cholera. Most outbreaks seem to be water-borne.

plex. Not everyone who takes the specific microörganism by the mouth necessarily gets the disease, but without it there can be no cholera. Many cholera vibrios probably die in the acid juices of the stomach. There is, therefore, perhaps less danger in taking small amounts of infection during active digestion than upon an empty stomach, for it has been shown experimentally that cold drinks do not stay long in an empty stomach, but pass quickly through the pylorus. After the cholera vibrio has passed the pylorus and reaches the alkaline juices of the intestines, it may find ideal conditions for growth or may still have a hard struggle for existence. Here symbiosis or antibiosis must play a dominant rôle. It is well known in all cholera epidemics that a deranged digestion is an important predisposing factor to the disease. An attack may thus be precipitated in healthy carriers. In the Hamburg epidemic a marked access of cases on Monday following the Sunday indiscretions was noted. Raw fruits, crude fibrous vegetables, and fermentable food, difficult of digestion, seem to favor the growth and multiplication of the cholera vibrio in the intestinal tract. In the light of this view such food may often be the predisposing factor rather than the medium which conveys the infection. Just what the factors are that favor or handicap the growth of the cholera vibrio in the intestinal tract are undetermined. Susceptibility to the infection also depends partly upon antibodies.

Pettenkofer stoutly maintained that the "comma bacillus" was only one of the factors in the etiology of the disease. He placed special importance upon the condition of the host and his environment, and considered at least three fundamental factors in his X, Y, Z theory: X is the germ, Y the host or soil, Z the environment. In this connection the disease may aptly be compared to fermentation, in which X represents the yeast, Y the carbohydrate, and Z the temperature, moisture, reaction, and other essential conditions for the growth and activity of the yeast. Pettenkofer maintained that X without Y and Z would not produce cholera, that is, while the cholera vibrio was pathogenic in India or Hamburg (1892), where Y and Z were favorable, it would be harmless in Munich, where Y and Z were unfavorable. To prove this theory, he and his assistant, Emmerich, drank pure cultures of cholera after first rendering the stomach contents alkaline. Pettenkofer, then an old man, soon developed a diarrhea; Emmerich had a choleraic attack. Pettenkofer did not regard his own case as cholera, and insisted that the inconclusive results lent confirmation to his theory of the importance of contributing factors (Y and Z). Metchnikoff and his pupils drank pure cultures of vibrios from four different sources and were able to produce true Asiatic cholera, which although mild had all the classical symptoms of the disease: rice water stools, subnormal temperature, vomiting, cramps, suppression of urine, and vibrios in almost pure culture in the stools. Similar convincing experiments have

occurred among laboratory workers, who have accidentally gotten pure cultures of cholera into their mouths. On the other hand, a number of persons who imitated Pettenkofer's experiment were not affected.

The cholera vibrio is an aërobic, liquefying, actively motile spirillum. It stains best with carbol fuchsin, 1 to 10. It grows well on ordinary culture media, but is very susceptible to acids and antiseptics. It is somewhat frailer than the average spore-free bacteria.

**Diagnosis.**—The diagnosis of cholera depends upon isolation and identification of the cholera vibrio in pure culture. This has become comparatively simple, but great care must be taken not to confuse the true vibrio of cholera with a great host of other microorganisms which closely resemble it.

A presumptive diagnosis of cholera may be made by finding large numbers of comma-shaped bacilli on direct microscopic examination of stained preparations, or in hanging drops of the mucous flakes ordinarily found in cholera stools. This test is only presumptive, the final criterion being the biological reactions of the microorganism obtained in pure culture. *The two reactions which are specific and reliable are Pfeiffer's phenomenon and agglutination.*

Dependence should not be placed upon morphological characters, cultural peculiarities, or pathogenicity upon laboratory animals, for these do not furnish the means of certainly defining the cholera vibrio. For the isolation of the cholera vibrio, agar is preferable to gelatin, formerly so much used. The suspected material should be planted upon the surface of ordinary alkaline agar or upon Dieudonné's medium, using one of the small rice-like flakes or an equivalent quantity of feces.

Dieudonné's medium is prepared as follows:

Sol. A.—Equal parts of a normal solution of potassium hydroxid and defibrinated ox-blood are mixed and sterilized in the autoclave.

Sol. B.—Ordinary nutrient agar, exactly neutral to litmus.

Seven parts of B are mixed with 3 parts of A and poured into Petri dishes. The plates should not be used immediately after their preparation. Dieudonné recommends keeping them several hours in the incubator at 37° C., uncovered and face down, or to heat them for 5 minutes at 65° C. Equally good results can be obtained by keeping them 48 hours at room temperature. The surface of the agar should be slightly dry. Once in condition, the plates should be used in a period not exceeding 5 or 6 days.

Upon this medium cholera vibrios grow abundantly. On the contrary, the organisms which most often accompany them on plate cultures, especially *B. coli*, grow either very poorly or not at all.

When it is suspected that the cholera vibrios are few in number, they may be enriched by first planting in Dunham's solution. Approximately 1 c. c. of fecal matter should be placed in 50 c. c. of the peptone solution.

This is incubated at 37° C., and in from 6 to 8 hours a loopful is taken from the surface and transferred to ordinary agar or Dieudonné's medium.<sup>37</sup> Suspicious colonies are fished and studied further. A quick method of detecting carriers is given on page 145.

Kolle and Gotchlich have shown from a large number of observations that with strongly agglutinative serum, the power of which reaches 1-4,000, the agglutinative power for common vibrios, not cholera, does not, as a general rule, exceed 1-50 and rarely reaches 1-200; agglutination in dilutions of 1-500 has been only very exceptionally observed. On the contrary, the true cholera vibrios agglutinate in dilutions varying from 1-1,000 and 1-20,000 and sometimes even higher. Therefore, with a specific agglutinating serum having a titer of 1-4,000, any organism which is agglutinated in 1-1,000 may be considered true cholera. Organisms agglutinating in dilutions of 1-500 should be regarded as doubtful.

In any critical case Pfeiffer's reaction (see page 576) should be tried. This is specific. See also page 145.

**Modes of Transmission.**—Cholera is spread by man from place to place. It follows the lines of trade and travel. Seaports are invariably first attacked. The epidemic at Hamburg in 1892 was brought to that port by immigrants on board vessels from Russia. There are many similar instances. In 1849 many a gold hunter found another Eldorado than the one he was searching for, as cholera was dragged across the continent by the caravans seeking fortunes in California. The same thing takes place in the Indian pilgrimages to Mecca.

The cholera vibrio enters the digestive tract through the mouth. It is taken in food and drink. Infected water is a frequent medium of transference, and probably the sole vector of the great epidemic outbreaks. Cholera, however, may be transferred from man to man directly, also indirectly by flies, fingers, food, and all the innumerable channels from the anus of one man to the mouth of another that have been described in the case of typhoid.

In endemic or residual cholera, water-borne infection plays a minor rôle. This was well proved in the sanitary campaign against the disease in the Philippine Islands, in which the water was practically ignored and the disease conquered in the light of a contact infection communicated rather directly from man to man. Convalescent carriers and healthy passive carriers are common means of spreading the infection.

The cholera vibrio leaves the body in enormous numbers in the dejecta, also sometimes in the matter vomited. The cholera vibrio is seldom found in the blood, but has been located in the gall-bladder and

<sup>37</sup> Some New Selective Cholera Media. Goldberger, *Hyg. Lab. Bull.*, 91, U. S. P. H. S.

other tissues. Disinfection in this disease must, therefore, be concentrated upon the discharge from the bowels and mouth, and also the urine at the bedside.

*Water.*—The cholera vibrio may live and even multiply in water. Koch in his original investigations found the organism in the foul water of a tank in India which was used by the natives for drinking purposes. It has been shown by experiment that the cholera vibrio may multiply to some extent in sterilized river water or well water; and that it preserves its vitality in such water for several weeks or even months. In recent times cholera organisms have been found not infrequently in the water of wells, water mains, rivers, harbors, canals, and even sea water (the North Sea near the mouth of the Elbe), which have become contaminated with the discharges of cholera patients. It is plain from the nature of the case that infected water must play a very large rôle in spreading this infection.

The earliest and now classic instance in favor of the water-borne theory we owe to Dr. John Snow. This is the classic Broad Street pump outbreak in London in 1854, an account of which will be found on page 1161.

The best example of water-borne cholera is the Hamburg epidemic of 1892, which I was fortunate enough to see in part. In this case no link in the chain of evidence is missing. Cholera was brought to Hamburg by immigrants from Russia. The water of the Elbe was infected with their discharges. The *Vibrio cholerae* was readily isolated from the river water which was distributed throughout the city for drinking purposes without purification. The sewers of Hamburg emptied into the river Elbe near the water intake, which produced a vicious circle. An account of the epidemic will be found on page 1165.

*Other Modes of Transference.*—The fact that water-borne infection is practically the only cause of the large cholera epidemics must not overshadow the importance of other modes of transmission. In addition to the violent outbreaks, cholera occurs in nests or smoulders like endemic typhoid. It is difficult to trace the connection between cases in endemic areas. Thus, a careful study of the cholera situation in Manila disclosed the fact that isolated cases would crop up at widely different points without any evident connection between them. Cholera carriers were suspected and later demonstrated. At irregular intervals of several years the disease would gather force, and cases multiply, until it assumed epidemic proportions, entirely independent, it is believed, of the water supply. The way cholera was dragged across our continent by the "forty-niners," and its occurrence among the Mecca pilgrims, are instances of its spread largely independent of infected water.

*Contact Infection.*—Contact infection in cholera must not be underestimated. Persons frequently become infected through handling

the dejecta or through freshly infected fomites, such as soiled linen. Direct transmission from person to person was formerly seen among physicians and nurses. In congested quarters, where many persons live under uncleanly conditions, contact infection plays an important part. The same thing may be seen on board vessels, in which case the disease may be confined to the firemen, stewards, or some other limited group who are required to live in close contact with each other. Epidemic outbreaks due to contact infection have been recorded, such as the 30 cases which occurred in the fall of 1892 in Boizenburg.

Cholera is not highly "contagious," for physicians, nurses, and others in close contact with patients need not become infected provided intelligent measures are adopted. On the other hand, there is great danger of the spread of the disease through devious and hidden routes, as is the case with typhoid and dysentery. Washerwomen and those who are brought in very close contact with the linen of cholera patients or with their stools may contract the disease. Koch, in his original investigations, found that the "comma bacillus" may multiply rapidly upon the surface of moist linen.

*Milk* may be contaminated, but is probably not a frequent medium of infection, for the reason that its acid reaction is inimical to the cholera vibrio. Green vegetables and fruit that have been washed in an infected water may convey the disease. The bacilli may live on fresh bread, butter, and meat for from 6 to 8 days, if not too acid.

*Flies, etc.*—It has been shown that the cholera vibrios may live in the intestines of flies for at least 3 days, and these and other insects may also spread the infection mechanically. The cholera vibrio is a frail organism and dies rapidly when dried or exposed to light and other injurious influences. Infection through the air is, therefore, not to be dreaded. Fomites, such as bed and body linen or other objects, including spoons, dishes, toys, etc., contaminated with the discharges, can be regarded as possible sources of infection. There is, however, a special limitation in this case, owing to the fact that this organism is so readily destroyed by desiccation and crowded out by saprophytic microorganisms. Thus, as a rule, only fresh dejecta and freshly contaminated objects are liable to convey the infection.

**Bacillus Carriers.**<sup>38</sup>—The cholera vibrios are passed in enormous numbers in the feces during the early part of the disease. They usually disappear after the fourth to the fourteenth day, but may remain one or two months. These are convalescent carriers. Chronic carriers are rare. Healthy or passive carriers occur and are an important and in-

<sup>38</sup> The recognition of the carrier principle in connection with the dissemination of various communicable infections was first established by Robert Koch in the course of his well-known investigations into the cholera outbreak which occurred in Germany during the winter of 1892-3. (*Zeitschr. f. Hyg.*, 1893, XV, p. 89.)

sidious means of spreading the infection; they may also develop the disease.

McLoughlin (1908) found bacillus carriers numerous in epidemic centers in the Philippine Islands. Thus he found 6 to 7 per cent. of carriers among healthy individuals living in the infected neighborhoods in Manila. On the other hand, carriers were exceedingly rare in neighborhoods having few cases. Cholera carriers, therefore, play a similar rôle to typhoid carriers in spreading the infection. Carriers are the principal factor in the spread of endemic cholera and they keep the infection alive in the Philippines, on Indian pilgrimages, and in other places where there is little or no water-borne infection.

In the outbreak of cholera in Manila, 1914, carriers were the most numerous and also the most insidious source of infection.<sup>39</sup>

*Detection of Carriers.*—Specimens are best obtained by administering a saline cathartic or by using a rectal tube with “eyes” cut into it.

Several different methods for the detection of cholera carriers are applicable. All of them are based upon the facility with which the vibrio grows upon Dunham’s solution. Particles of feces are planted in this medium and subsequently examined for comma-shaped microorganisms. If found, the diagnosis is presumptive. Pure cultures should then be made and studied for agglutination. Details of the method are the same as described on page 141.

The routine bacteriological examination of immigrants from cholera-infected ports, as practiced at the Quarantine Station at New York, in 1912, was as follows:<sup>40</sup>

1. Inoculation of feces into Dunham’s peptone solution (at 37° C.).
2. Subinoculation at the end of six hours of one loop of the surface growth into a second Dunham’s peptone tube.
3. Examination of a smear taken from the surface growth of the second Dunham’s peptone tube, after incubation 6 to 9 hours at 37° C.

Bendick uses a modified Dunham’s solution containing sodium carbonate, 1 gram; saccharose, 5 grams; and phenolphthalein solution, 5 c. c., in addition to the usual amount of water, peptone and salt. The cholera vibrios ferment the saccharose; the acid produced unites with the sodium carbonate and the medium becomes neutral, hence the red color of the phenolphthalein disappears.

**Immunity and Prophylactic Inoculations.**—The immunity produced by an attack of the disease is of short duration. An active immunity may readily be induced in susceptible animals against cholera vibrios. Attempts to immunize man with cholera vaccines were made by Ferran in Spain in 1884, and Haffkine in India in 1895. These early attempts did not produce a high degree of immunity, and the results were not

<sup>39</sup> *Philippine Jour. Sc.*, Sec. B., Trop. Med., 1915, X, p. 1.

<sup>40</sup> Bendick: *Jour. of Am. Pub. Health Assn.*, I, No. 12, 906, Dec., 1911.

conclusive. It has since been shown by Kolle, Powell, Simpson, Wright and others that prophylactic vaccines against cholera are a practical and useful method of protection. Convincing figures are not readily obtainable, but all observers are assured of its usefulness. Cholera vaccines, either alone or mixed with typhoid vaccines, were much used in the war to protect the troops serving in districts where the disease prevailed. Cholera vaccines have been much used in Japan, where good results are reported. Most of the inconclusive results were due to using too small a dose or not giving a sufficient number of inoculations.

Haffkine used live cultures attenuated after the principles of Pasteur. He first injected a culture weakened by prolonged cultivation in artificial media at 39° C.; a second injection was given of a culture which had been rapidly passed through animals. He subsequently modified his method to a single inoculation of a virulent culture recently recovered from the peritoneum of a guinea-pig. The dose for an adult is 0.5 c. c. of an emulsion of an agar slant in 5 c. c. of sterile water, injected subcutaneously. It is not possible to produce cholera by introducing the spirilla parenterally.

Kolle uses a more practical method, standardized so that one c. c. of the suspension contains 2 milligrams of culture. The vibrios are grown on agar slants, suspended in salt solution and then heated to 58° C. for one hour; 0.5 c. c. of phenol is added as a preservative. One c. c. (2 milligrams of culture) is given subcutaneously, 3 or 4 times, at intervals of 5 to 7 days.

The immunity produced by these protective inoculations lasts about a year, when the specific antibodies begin to diminish in the blood serum.

There seems to be little doubt in Japan concerning the value of the protection afforded by the inoculation of dead cultures, for in the district of Hiogo, during the epidemic of 1902, 77,907 persons were inoculated. Of these 47, or 0.06 per cent., took cholera, and 20, or 0.02 per cent., died, whereas, among 825,287 persons not inoculated, 1,152, or 0.13 per cent., took the disease, and 863, or 0.1 per cent., died. It is especially noteworthy that all the cases among the inoculated group were in those who received an injection of 2 mg. of the dead culture. Later 4 mg. were used, and in this group no cases occurred. Good results were also obtained in the Russian epidemic of 1908-9, and in the World War.

Protective inoculations as a prophylactic measure against cholera will never be popular or necessary in communities with sufficient sanitation. It is, however, of value in camps, armies on the march, for physicians, nurses, ward tenders, travelers, and others especially exposed.

**Quarantine.**—Cholera is an infection which fully justifies maritime quarantine practice. The disease may be blocked by a careful system of inspection, detention, and disinfection at the seaport. In order for mar-

itime quarantine to be effective for cholera, it must have the assistance of a bacteriological laboratory to diagnose cases and recognize carriers. A bacteriological examination of the feces of all persons coming from cholera-infected places has entirely supplanted the old-fashioned period of indiscriminate detention for five days.

In the summer of 1912 the quarantine authorities at the large sea-ports on our Atlantic littoral examined about 34,000 specimens of bowel discharges from passengers and crews from cholera-infected ports. At the New York quarantine the cholera vibrio was isolated from 28 persons sick with the disease, and 27 healthy persons were found to be discharging vibrios in their feces. These carriers could not have been discovered except by laboratory examination. Seven cases of cholera were detected at other ports by the same methods. There can be no doubt that the adoption of this measure kept cholera out of the country.

Similar measures used at the port of departure can be successfully applied. Owing to the fact that most cholera carriers soon purge themselves of the vibrios, the detention in quarantine is ordinarily not prolonged. Three or more negative bacteriological findings at intervals of two days should be required before releasing a carrier (see page 503).

**Personal prophylaxis** requires, first of all, scrupulous cleanliness on the part of the person and his surroundings. Those who handle cholera patients, their dejecta, or infected articles must carefully disinfect their hands each time, and should under no circumstances eat or drink anything in the sick room. During cholera times all water and food of every description should be boiled or thoroughly cooked just before it is partaken. Great care must be exercised that the water or food does not become infected after it has been boiled or cooked. The usual measures should be taken to guard against flies and other vermin. With strict attention to these measures, it is possible to avoid the infection. In addition, however, attention to general hygiene and especially to the character of the food and regularity of meals should be given. Slight attacks of indigestion and diarrhea should receive prompt medical attention. Those exposed should protect themselves with cholera inoculations. The disinfection of fecal discharges and other special measures are the same as for typhoid fever.

A summary of the preventive measures necessary to control an epidemic of cholera are: centralization of authority in one person; establishment of a system of securing and reporting information; organization of the personnel for the sanitary work; enactment of necessary ordinances; house to house inspection; safe disposal of feces of entire population; provision for a safe water supply; supervisory control of food and drink; a search for, and control of carriers; isolation and care of patients in special hospitals; separate hospitals or wards for suspects; a laboratory; detention camps or barracks for those desiring to leave the infected

area; disinfection, etc. For further discussion concerning the control of epidemics, see page 495.

## DYSENTERY

(*Flux*)

Dysentery is a form of intestinal flux, characterized by frequent passages of blood and mucus, and straining at stool. Diarrheas of this type may be due to several causes, and for the purpose of prevention we may consider all dysenteries under three heads: (1) Bacillary, due to *B. dysenteriae*; (2) amebic, due to *Entameba histolytica*; and (3) symptomatic, due to a variety of irritating poisons.

### BACILLARY DYSENTERY

*Bacillary dysentery* is a specific infection caused by *Bacillus dysenteriae*, of which there are a number of strains. It is usually a self-limited disease, running an acute course without complications or sequelae. Bacillary dysentery occurs in all countries and climes, with a tendency to summer prevalence. All grades of severity are met with, and the case fatality rate varies greatly, often running as high as 30 per cent. Bacillary dysentery increases in amount and severity as we approach the Equator, but severe outbreaks occur in temperate and even in Arctic regions. It affects all ages and is one of the chief causes of summer diarrheas in infants. The disease occurs as great epidemics, in local outbreaks and sporadically. In all armies up to recent times it has caused great ravages. Dysentery bacilli have killed many more soldiers in the world's history than bullets. In the Federal Service during the Civil War, there were 259,071 cases of acute dysentery. Practically all epidemics of dysentery in camps and institutions are bacillary. Overcrowding, lack of cleanliness, and other unhygienic conditions favor its spread so that it is called famine, asylum, jail, ship, or camp dysentery.

*B. dysenteriae* is a gram-negative, spore-free, non-liquefying bacillus belonging to the typhoid-colon group. There are at least four different groups or strains: Shiga, Flexner, Strong, and Y. The Flexner type is most frequently found in the United States. The symptoms and lesions produced by the different strains are identical. See table, page 700. A strong toxin may be obtained from the Shiga strain which when injected intravenously into rabbits produces a fatal toxemia with a faithful reproduction of the symptoms and lesions of bacillary dysentery. Two toxic substances have been demonstrated by Olitsky and Kligler<sup>41</sup> in this toxin: (1) an exotoxin, which acts especially upon the nerves

<sup>41</sup> *Jour. Exp. Med.*, 1920, XXXI, 1, p. 19.

and is therefore called a neurotoxin; (2) another, which is probably an endotoxin, acts upon the intestinal tract and is therefore called an enterotoxin.

**Resistance.**—The dysentery bacillus has about the same resistance to germicides and other unfavorable conditions as the general class of spore-free bacteria. It dies in about 8 to 10 days when dried. It may live for months when moist. It is sensitive to acids. Phenol, 0.5 per cent., kills the dysentery bacillus in 6 hours. 1 per cent. in 30 minutes, 3 per cent. in 1 to 2 minutes. Bichlorid of mercury, 1-1,000, kills it at once, and direct sunlight in about one-half an hour. I have found certain strains of the dysentery bacilli somewhat more resistant to heat than the typhoid bacillus. They are killed with certainty at 58° C. for one hour, or at 60° C. for 20 minutes. The dysentery bacillus resists cold and may live for months when frozen.

*Bacillus-carrying* in dysentery occurs, and probably plays a more important part in spreading the disease than we now suspect. As a rule, the bacilli soon disappear from the stools in the light cases, but they may persist from 2 to 6 weeks after clinical recovery. Shiga has found them more persistent in some instances. Von Drigalski reports an outbreak in Germany caused by a returning soldier. Recent convalescents may spread the infection. Permanent or chronic carriers have not been discovered. In 1917, the feces of over 2,000 healthy persons in and around Boston were examined in my laboratory without finding a single dysentery carrier.

**Immunity.**—The susceptibility to dysentery varies greatly. This is doubtless due in part to the bacterial flora of the intestinal tract as well as the conditions of the intestinal mucosa. Symbiosis or antibiosis must play a very important rôle either in permitting or hindering the growth of the dysentery bacillus in the intestinal tract. There is still a question whether a true immunity is acquired by one attack of bacillary dysentery. This seems probable, although it is not unusual for a person to have two or more attacks of dysentery in one season. Kolle looks upon this as an exacerbation of a chronic type brought on by errors of diet, exposure, etc. The experiments on animals indicate that dysentery probably belongs to that group of diseases which leave a certain amount of protection after one attack. A definite and high grade of immunity can be produced experimentally in several of the lower animals. Upon this question, however, we need light. Horses may be immunized to a high degree, and their sera contain a certain amount of antitoxin and other antibodies. This serum has been used in treatment, but has no particular value as a preventive. There is no immunity in amebic dysentery.

The methods of spread and prevention of dysentery are an exact counterpart of those of typhoid fever: food, fingers, flies, contacts and

carriers play a rôle. Milk-borne and water-borne outbreaks have been traced.

Bacillary dysentery is a common disease in infants, and it would be a wise precaution to consider all cases of infantile diarrhea as infectious and to take precautions accordingly. The protection of babies against dysentery requires biologic cleanliness, sanitary isolation, and a ceaseless and intelligent technique. Dysentery is one of the greatest single factors in high infant mortality (page 1275).

Dysentery vaccinés have definite protective value, and were used among certain troops during the World War. Convincing figures are difficult to obtain, but the protective value seems obvious.

### AMEBIC DYSENTERY

*Amebic dysentery* (amebiasis, tropical dysentery) is caused by the *Entameba histolytica*, and is characterized by a colitis with tendency to chronicity, and a special liability to the formation of abscesses of the liver (amebic hepatitis). Ipecac and its alkaloid emetin have curative virtues. Amebic dysentery often starts insidiously and shows a tendency to become chronic, with exacerbations and relapses; acute attacks occur. The parasite is taken in by the mouth and passed by the bowels. There is no immunity.

Amebic dysentery is more severe and more frequent in the tropics, and in subtropical climates, but cases are surprisingly widespread through the temperate zones and even in arctic regions. The classical report of Losch,<sup>42</sup> 1875, recorded the case of a patient with amebic dysentery in St. Petersburg, Russia. Cases have been also reported in Alaska.<sup>43</sup>

Amebic dysentery occurs mainly in endemic form, rarely in epidemic proportions. This is perhaps due to the fact that the amebas are transferred almost always by rather direct and intimate contact. Food infection may occur, but is not the cause of explosive outbreaks, such as we see in typhoid fever and bacillary dysentery. Milk and water-borne outbreaks of amebiasis do not occur as in the case of bacillary dysentery.

*Entameba histolytica* may be found, sometimes in great numbers, in the discharges from the bowels and in the pus from liver abscesses. There are two chief amebas in human feces—the pathogenic variety (*Entameba histolytica*) and a harmless form (*Entameba coli*). The pathogenic form, *Entameba histolytica*, is distinguished from *Entameba*

<sup>42</sup> *Massenhafte Entwicklung von Amoben im Dickdarm, Virchows Arch. f. path. Anat.*, 1875, LXV, 196.

<sup>43</sup> Axtell, W. H.: "Amoebic Dysentery Contracted in the Arctics of Alaska: Report of a Case." *Northwest. Med.*, 1911, N. S., III, 51.

*coli* by the fact that the pathogenic form usually has not more than four nuclei in the encysted stages, whereas *Eutameba coli* shows typically eight nuclei; for the positive differentiation between these two species it is important to distinguish the encysted forms. This difference is absolute. The following are relative: The pathogenic forms are (1) larger size, (2) greenish color, (3) distinct hyalin, with refractile ectoplasm, (4) have a faint nucleus, (5) many vacuoles and red blood cells, (6) marked motility, with pseudopodia of clear ectoplasm.

*Eutameba histolytica* is an obligate parasite. It has a comparatively simple life cycle, with no free living stage. The motile amebae are very frail, but the encysted form which appears later in the disease and in carriers is more hardy. The encysted form is infective and dangerous. It is specific for man. Kittens may be infected by injecting the infectious material directly into the cecum.<sup>44</sup> None of the parasitic amebae have yet been successfully cultivated upon artificial media.

Emetin, one of the alkaloids of ipecac, is quite as specific for amebic dysentery as quinin is for malaria. Large doses of ipecac have been used for many years in the treatment of dysentery, particularly by English practitioners in India. The difficulty has been in inducing patients to retain a sufficient amount of the drug by the mouth. Pelletier, in 1878, described an alkaloid in ipecacuanha which he called "emetin." Rogers in 1907 demonstrated that this alkaloid would rapidly cure an amebic hepatitis in the presuppurative stage, and thus prevent the formation of liver abscess. Rogers first used emetin subcutaneously in June, 1912. It is now clear that emetin, when so administered, promptly causes a disappearance of the motile forms of the ameba from the feces, but has no effect whatever upon the encysted forms; it promptly relieves the symptoms, but does not cure or prevent ameba carriers; it does not prevent relapses, but cures them when they occur. Emetin hydrochlorid is given intramuscularly in doses of about  $\frac{1}{2}$  grain every 3 hours for 3 to 6 days; repeated if necessary. Emetin-bismuth iodid and also Chapparo amargoso are useful.

The prevention of amebic dysentery consists in a search for and control of carriers, also mild, latent and chronic cases. These should be treated with injections into the colon of solutions of quinin, kerosene and other amebicides. Emetin does not kill the encysted stage, and hence will not cure carriers.

**Contrast between Bacillary and Amebic Dysentery.**—There are fundamental distinctions between these two diseases, which are summarized in the following parallel columns:

<sup>44</sup> Sellards and Baetjer, *Am. Journ. Trop. Dis. and Prev. Med.*, II, 4, October, 1914, p. 231.

BACILLARY DYSENTERY	AMEBIC DYSENTERY
Cause— <i>Bacillus dysenteriae</i> .	Cause— <i>Entamoeba histolytica</i> .
An acute, febrile, self-limiting disease with severe toxemia. (Sometimes very mild.)	An insidious and chronic infection, often afebrile, and little or no signs of toxemia. (Sometimes acute with fever.)
Lesions are diffuse in the large intestines, and sometimes occur in the small intestines. Varies greatly in severity.	Lesions localized in large bowels, never in the small intestines. Ulcers undetermined.
Few sequelae.	Liver abscess common sequela.
Incubation—2 to 7 days.	Prolonged and variable.
Definite immunity.	No immunity.
Chief cause of infantile "diarrheas."	Uncommon in children in the temperate zone.
Vaccines are protective.	No specific prophylactic is known.
Temporary active carriers play a rôle, but probably are not the chief agent in spread. Chronic carriers are rare.	Chronic carriers frequent and play chief rôle in spreading infection.
Epidemics frequent and often widespread. Frequent outbreaks in institutions. The disease is called jail, asylum, camp, and ship dysentery.	An endemic disease; does not occur in epidemic outbreaks.
Most prevalent and most severe in tropical and subtropical countries. Widespread in temperate climes.	Same geographic distribution; less common in temperate and cold climes.
Mode of spread—like typhoid; water, milk, food, flies, fingers, contacts, carriers, etc.	Spread by intimate personal contact. Water, milk, and food outbreaks not known.
No specific cure.	Emetin cures symptoms.

Dysentery should be included in the notifiable diseases and laboratory aid furnished by Boards of Health to assist diagnosis. Cases should be isolated in the same sense that cases of typhoid are isolated, and disinfection practiced at the bedside. Outbreaks in institutions should always be investigated and vigorous measures taken to check further spread and to prevent recurrences. In all respects the prevention of dysentery is a close parallel to that of typhoid.

**HOOKWORM DISEASE***(Uncinariasis or Ancylostomiasis)*

Theoretically the prevention of hookworm disease is comparatively simple, for here we have an infection of which we know the parasite and its life history, its mode of exit and entrance into the body, and we possess a satisfactory cure for the disease within reach of all. Practically, however, we have ignorance, apathy, poverty, and uncleanness to deal with before satisfactory prevention, much less eradication, can be achieved. It is now plain that hookworm disease presents a sanitary problem of first magnitude, not alone in our southland, but in practically all tropical and subtropical countries. Further, there is a large economic and industrial aspect to this question in medical biology.

**Distribution.**—Hookworm disease encircles the globe in the tropical and subtropical climes; it diminishes toward the temperate regions. It is not endemic in the colder latitudes, except in mines, especially those of Wales, Germany, Netherlands, Belgium, France, and Spain. The infection belts the earth in a zone about 66° wide, extending from parallel 36 north to parallel 30 south latitude. The amount of infection is great in American Samoa, where it is found in 70 per cent. of the population; in the southern two-thirds of China, in 75 per cent. of the population; in India from 60 to 80 per cent. of the 300,000,000 population have the worms; in Ceylon, 90 per cent. in many parts; in Natal, 50 per cent. of the coolies on sugar and tea estates; in Egypt, 50 per cent. of the laboring class; in Dutch Guiana, 90 per cent. in many parts; in British Guiana, 50 per cent. of all; in Colombia, 90 per cent. of those living between sea-level and 3,000 feet, which includes most of the population; in 1904 the Porto Rican Anemia Commission found that 90 per cent. of the rural population of that island were infested. Stiles estimates that in this country 2,000,000 individuals have the parasites from the Potomac to the Mississippi, along the Atlantic littoral and the Gulf states. In some German mines from 30 to 80 per cent. of the miners have been found to be infested. Gunn<sup>45</sup> has shown that from 50 to 80 per cent. of those working in the California mines harbored hookworms in 1911. It is probable that all the older mines employing foreign laborers sooner or later become endemic foci.

In 1879 an outbreak of hookworm disease occurred among the laborers in St. Gothard's tunnel and was called miner's anemia. This aroused the interest of the scientific world. The polluted soil of the tunnel was found to be impregnated with the eggs and larvae. Interest in the disease in this country was aroused through the work and enthusiasm of Stiles.

<sup>45</sup> *Jour. A. M. A.*, Vol. LVI, No. 4, Jan. 28, 1911, p. 259.

**Species of Hookworm.**—Many mammalian animals have hookworms, but in general each host species has a different kind of hookworm; that is, the hookworms of the dog, sheep, horse, the seal, etc., differ from each other, and are specific. The common hookworm of the dog in this country will not infest man; the hookworms of man do not as a rule develop to maturity in the lower animals.

Three species<sup>46</sup> of hookworm are found in man—the old world form (*Ancylostoma duodenale*) and the Ceylon hookworm (*Ancylostoma ceylanicum*); and the new world form (*Necator americanus*). The distinction between these worms has a zoölogical rather than a practical bearing, for all three produce the same symptoms, require the same treatment, have the same life history, and call for the same preventive measures.

The chief differences between the two genera of hookworms of man consist in the fact that *Ancylostoma* has one pair of ventral hooks, two conical dorsal teeth, and the posterior ray of the caudal bursa divides two-thirds its way from the base, and each division has three tips (tripartite), while *Necator* has ventral lips, a dorsal median tooth, one pair of dorsal and one pair of ventral lancets deep in the buccal capsule, and the posterior ray of the caudal bursa divides at its base and each division has two tips (bipartite).

According to Stiles, the vast majority of cases of hookworm disease in man in the United States are due to the new world form (*Necator americanus*).

**Modes of Transmission.**—The usual mode of transmission, perhaps in 90 per cent. or more of the cases, is through the skin. The embryos may also be taken by the mouth in drinking water or solid food, or from contaminated objects, such as dirty fingers. It has been shown by experiment that animals can be infected by drinking water containing the embryos. While this source of infection plays a minor rôle, it is not to be disregarded.

The infection leaves the body exclusively in the feces, which contain the eggs of the parasite.

**The Parasite.**—For a correct understanding of the prevention of hookworm disease it is necessary to have a knowledge of the essential features of the life history of the parasite.

Hookworms are round worms (nematodes) belonging to the supra-family *Strongyloides*. The adult worm is about one-half to three-quarters of an inch long, and about the diameter of a wire hairpin.

The adult hookworm lives in the intestinal tract, usually in the small intestine. It attaches itself to the intestinal wall, wounds the mucosa, sucks blood, eats the epithelium, and probably produces a toxic substance which injures the host.

<sup>46</sup> Two genera—*Ancylostoma* and *Necator*.

The female worm lays a prodigious number of eggs in a never-ending stream, which pass from the host in the feces. The embryo does not mature within the egg except in the presence of oxygen. Hookworm embryos, therefore, do not undergo full development until the eggs are discharged into the outer world. On the other hand, *Strongyloides stercoralis*, the parasite of Cochin-China diarrhea, develop embryos which escape from the shell and are passed in the stools. The hookworm embryos become mature within the egg in 6 to 8 hours in the presence of favorable conditions of moisture, warmth, and oxygen. It is, therefore, necessary to

FIG. 14. — HOOKWORMS, NATURAL SIZE.

examine the fresh stools in order that this difference between the two infections may be of value in differential diagnosis.

Under favorable conditions the hookworm embryo escapes from the egg and becomes a larva in about 24 hours. This free-living embryo exists and moves in moist soil and feeds upon the organic matter found there. In the course of two days or more it sheds its skin (undergoes ecdysis) and thus passes to the first molt. The resulting larva continues as a free-living parasite, and in about a week again sheds its skin, but now continues to live encysted inside this discarded skin. This is the second ecdysis and this encysted larva no longer takes food. This stage in the life history of the parasite is of special importance for the reason that it is capable of piercing the skin; that is, it is the infecting stage. In this condition the parasite may continue its free living existence for 5 to 12 months, perhaps longer. The larva has a slow motion and under favorable conditions probably travels a number of yards, increasing the radius of soil pollution.

The hookworm larva passes in all through four ecdyses or molts. Two of them occur during its free-living stage and two of them during its residence in the host. With each ecdysis the larva approaches more nearly the appearance and structure of the adult worm.

The larva pierces the skin and passes by a circuitous route to the intestinal tract. The parasite may enter the skin at any place, but it usually goes through the soft and thin skin between the toes. In its

FIG. 15.—HOOKWORM EMBRYO.

passage through the skin the larva produces an inflammatory reaction (ground-itch) which results partly from the irritating action of the presence of the foreign body, but mainly from the bacteria carried along with the larva. These primary lesions may consist of a few itching papules or pustules to a severe dermatitis. Of 4,741 patients questioned by Ashford, King, and Guterrez in Porto Rico, 4,664, or about 98 per cent., gave a history of ground-itch, which is now recognized as the first stage of the disease.

The fact that the infection with hookworm disease is usually contracted through the skin was discovered by Looss in Cairo, Egypt. He also unraveled the course of the parasite from the skin to the intestine. This brilliant discovery, which is one of the romances of medical biology, is the foundation upon which prevention against the infection depends. In 1895 Looss accidentally spilled a drop of water containing many encysted larvae upon his hand, and noted that they disappeared, leaving their delicate sheaths behind them. Seventy-one days subsequently he developed intestinal uncinariasis. The experiment was then repeated upon a volunteer, and hookworm eggs appeared in his stools in 74 days. Claude Smith found eggs in the feces 6½ weeks and 7 weeks after experimental skin infection on two persons with the American parasite (*Necator americanus*).

The wanderings of the parasite from the skin to the intestine were worked out by Looss partly by placing larvae upon an amputated leg and also by studying the question upon puppies. The hookworm larva usually pierces the skin through a hair follicle, enters the subcutaneous tissue, and then finds its way through the lymphatics to the neighboring lymph nodes. The larvae are able to squirm through the lymph nodes, pass to the thoracic duct, and thence to the vena cava and the right heart. From the right heart they are carried in the blood stream to the lungs. The larvae are too large to pass the capillaries of the lungs. They pierce the capillary walls and appear in the alveoli and are now, to all intents and purposes, again in the outer world. They pass up the bronchi and trachea to the throat, whence they are swallowed, and finally lodge in the small intestines. During their travel through the body they pass through two ecdyses.

The adult worm attaches itself to the mucous membrane by means of the powerful buccal lancet. The epithelium is drawn into the buccal cavity as though by a powerful suction. The worms are usually found in the small intestine, especially in the jejunum, less often in the duodenum, and rarely in the ileum and lower reaches of the intestinal tract; they are occasionally met with in the stomach.

The parasites imbibe large amounts of blood, some of which passes through the worm unaltered. The wound continues to bleed after the worm releases its hold, owing perhaps to a hemolytic substance in the

month parts of the parasite. The worm does not remain fastened to one place indefinitely, but releases its hold and attaches itself anew. This produces numerous minute wounds, favoring secondary infections. The hookworm probably produces a poison which is absorbed and which accounts, in part, for the anemia and other symptoms of the disease. The severity of the symptoms probably bears a definite relation to the number of worms. A few hookworms rarely produce clinical evidence of their presence. The number varies greatly in individual cases; from one or two to thousands. Sandwith counted 250 worms and 575 bites in one case; 2,000 worms are not an uncommon number. The Porto Rican Anemia Commission counted as many as 4,600 passed by one individual.

**Immunity.**—There is no acquired immunity to this disease. There is, however, a racial resistance to the effects of the infection, as shown by the negroes and the Filipinos, who are often infested but have comparatively slight symptoms. Stiles found that in this country the negro is a reservoir for hookworm disease in that while he is frequently infected he is but slightly affected when compared with white patients. Perhaps the negro has had the disease so many generations in Africa that he has become relatively immune. It is conjectured that the infection was brought to America through the negro slave trade. Hookworm disease lowers resistance and greatly increases the effects of other infections, especially tuberculosis. The secondary results are often more disastrous than the primary effects.

**Resistance of the Parasite.**—The adult worm in the intestinal tract may be benumbed or killed with thymol, betanaphthol, chloroform, chenopodium, eucalyptus oil, and other vermifuges.

From the standpoint of prevention, it is more important to know the resistance of the eggs and larvae during their free-living stages. Stiles and Gardener have shown that the soil under and around privies is not entirely free from infection with hookworm even five months after the privy was last used, although the infection is considerably reduced at the end of four months. When the fecal matter has undergone decomposition under water most of the hookworm eggs are dead in about ten weeks, though some still survive, but probably all are dead in three months. It would not be safe to use such material as a fertilizer in less than three months. The encysted larvae may live in water several months.

The larvae are readily killed by dryness and freezing. The infection was once considered to be dust-borne, but the fact that the parasites are killed by drying renders the danger from dust negligible. The fact that freezing kills the eggs and larvae largely explains why the disease is not endemic in this country north of the Potomac.

It has been shown that chlorinated lime fails to kill hookworm eggs in 23 to 40 hours. Schüffler kept the larvae alive almost four months in

water with two or three drops of a one per cent. quinin solution to 10 c. c. Oliver found that sea water killed the larvae in 37 minutes.

**Prevention.**—The prevention of hookworm disease consists in preventing pollution of the soil and in treating existing cases so as to diminish the amount of infection. The principles of prevention are easy in theory, but their application is difficult in practice on account of the widespread and enormous amount of the disease. The suppression of hookworm disease means the social and economic uplift of nations, the education of millions of people, and an entire change in their daily hygienic habits. Education of the masses is an important factor, calling for coöperation between the health authorities, civic forces, the medical profession, schools, and philanthropic agencies; it is something for the preacher and teacher.

*Soil Pollution.*—The prevention of soil pollution is the essential factor; it is the key to the situation. This one line of prevention could blot hookworm disease out of existence. This requires not only the building of proper privies, and insisting upon their being used in country districts, but also the Mosaic method of burial of feces when defecating in fields or woods.<sup>47</sup> In warm countries direct pollution of the soil is much more common and also much more dangerous than in cold countries. Add to this the custom of going barefooted and we have all the factors necessary for the dissemination of hookworm infection.

Stiles estimates that about 50 per cent. of the rural homes in the South are without privies. Even many schools and churches do not have these accommodations, and are, therefore, hotbeds of infection. For the care and disposal of night soil see chapter on Sewage.

*The Eradication of the Infection in Man.*—Hookworms may be expelled from the intestinal tract by the use of thymol, oil of chenopodium, betanaphthol, or certain other anthelmintic. The eradication of the infection through the treatment of all infected persons is an essential factor in preventive measures.

*Thymol.*—The usual treatment is as follows: Saturday evening a full dose of magnesium sulphate is given to permit direct access of the thymol to the worms, which are often imbedded in the mucus or chyme. The object is to treat the parasite and not the host. On Sunday morning, at 8 o'clock, 2 grams (30 grains) of thymol, for an adult, finely powdered in capsules, are given by the mouth. Two hours later, at 10 o'clock, 2 more grams are administered; and at 12 o'clock another dose of salts (never castor oil). On account of occasional cases of idiosyncrasy to thymol, Stiles prefers to divide the total dose (60 grams for an adult) into three portions,

<sup>47</sup>The cat usually buries its feces and as a result it rarely has hookworm infection; dogs do not usually bury their feces and as a result hookworms are common in these animals.

which are administered at 6, 7 and 8 o'clock, followed by salts at 10. The dose for children should be based upon the apparent rather than upon the actual age. During the treatment it is important to avoid alcohol, fats, and oils, as thymol is soluble in these substances and may, therefore, be dangerous, as they favor absorption. The treatment is repeated every Sunday until the eggs disappear. Usually two or more treatments are necessary. Roughly speaking, about one-half of the cases clear up in three treatments, 90 per cent. in five treatments, and it is necessary to administer drugs to the other 10 per cent. anywhere from 6 to 20 times, according to the case. A microscopic examination of the feces for eggs will determine when the treatment has been effective; this examination should not be made until a week after the treatment, as thymol frequently inhibits the egg-laying by the worm.

*Chenopodium*.—On account of the World War, the supply of thymol became nearly exhausted, and oil of chenopodium came into widespread use in hookworm disease. This drug is undoubtedly a powerful anthelmintic, but, like thymol, it should be used with discretion. Unfortunately it is not always of uniform strength and toxicity. If redistilled, the lighter distillate is more powerful as an anthelmintic and is less poisonous than the heavier distillate. There are many different methods of administering it, and authors are not agreed as to whether it is better to follow it with salts or with castor oil. Laboratory experiments by Hall are distinctly in favor of castor oil, but some prominent clinicians prefer to use salts. It is important to recall that chenopodium inhibits peristalsis, hence increases constipation; accordingly, prompt purgation is important in order to avoid poisoning. Chenopodium is also a cardiac and respiratory depressant and has an effect on the kidneys, occasionally producing nephritis. Despite these objections, it is an exceedingly valuable drug if properly used, and it bids fair to equal or surpass thymol in popularity. It is certainly preferred to thymol by the patients and it is more efficient against hookworm and *ascaris*. As it strongly inhibits oviposition the reëxamination of the stools for eggs should be postponed for 14 days after treatment. As it is cumulative in effect, the treatments should not be repeated oftener than once a week, better two weeks. Authors are not entirely agreed as to dosage, but experience seems to indicate that the total daily maximum dose for an adult is 3 c. c., and that half the maximum dose (1.5 c. c. given three times in doses of 0.5 c. c.) is best as a routine vermicide. The International Health Board<sup>48</sup> uses 1.5 c. c. in 2 doses; thus, 0.75 c. c. at 6 A. M., 0.75 c. c. at 8 A. M., and a large saline purge at 10 A. M. No preliminary dieting is necessary. Oil of chenopodium will eliminate 90 per cent. of hookworm and *ascaris*. Detailed tables of doses for the different

<sup>48</sup>Darling: *J. A. M. A.*, Feb. 23, 1918, LXX, p. 499; also, *Lancet*, 1920, II, 69.

age groups have been worked out by several authors: for instance, 2 to 12 years, 1 minim for each year minus 1 minim (example, 6 years, 5 minims); 13 and 14 years, 13 minims; 15 to 16 years, 16 minims; 17 to 18 years, 20 minims; 19 to 20 years, 24 minims.

**Plan of a Hookworm Campaign.**—The eradication of the infection in man was carried out on a wholesale scale by the Porto Rican Anemia Commission, consisting of Ashford, King, and Gutierrez. Their methods were highly successful and have served an equally useful purpose in other places. They established a clinic for the microscopic diagnosis and free treatment of the disease. The good results of treatment spread rapidly, so that the facilities of the clinic were soon taxed to its utmost capacity. Not the least important function of the clinic was to educate the profession as well as the people. In a little while the clinic was moved to another point, and so on, until it gradually covered the entire island. The same general plan was used in the south and is used now in various other parts of the world, especially by the International Health Board.

**Education.**—Education is one of the most important factors in eradicating hookworm disease, for the reason that its final control depends upon improvements in the sanitary habits of the people, especially in the rural districts. To change the daily habits of half a nation is an uplift that requires time and patience. It is perhaps best to begin with the school children; even then it will take a generation for results. Very little can be accomplished by force, and, if the customs and prejudices of the people are ignored, the reformer and benefactor meet with rebuff and failure. It is a good idea to have a public health day or a public health week in the schools, during which time lectures and educational work upon hookworm, typhoid, tuberculosis, and other prevalent infections are considered. The children carry the lesson into the home. Pamphlets, posters, lectures, exhibits, and popular articles in the magazines and newspapers all contribute their share. The medical profession in the infected areas may need instruction and a little prodding to awaken interest in the problem. In the popular education on health matters the medical profession should lead, especially through the health authorities. This has also become one of the manifest duties of the practitioner.

**Cleanliness.**—After all, the prevention of hookworm disease is a question of decency and cleanliness. Water sometimes carries the infection, hence it should be clean or cleansed by filtration or boiling. Soiled hands may carry the infection to the mouth, hence they should be washed before eating. Vegetables fertilized with night soil may be infected. This practice is not clean and should be forbidden, especially in the case of those vegetables usually eaten raw. With cleanly habits there would be no soil pollution, and the disease would be checked.

**Personal Prophylaxis.**—Personal prophylaxis consists in wearing

shoes and otherwise avoiding contact with the infected soil. Miners, brick makers and others compelled to work in infested soil may wear gloves. Other measures, such as boiling the water, eating only cooked or clean food, washing the hands, and avoiding the infected area, have either been dwelt upon or are too obvious to need further emphasis.

*Immigration.*—An important factor in the spread of hookworm disease in the United States is immigration. Every country that brings laborers from hookworm regions is bringing in a constant stream of infection. California has established quarantine measures against Indian coolies, 90 per cent. of whom are infected.

**Collateral Benefits.**—The best part of a hookworm campaign is the collateral good it does. This applies as well to a sanitary campaign directed against almost any disease. The suppression of hookworm disease will diminish the amount of tuberculosis, typhoid fever, dysentery, and other infections. Thus, in Bilibid prison, Manila, the death rate was formerly excessive—234 per thousand when the Americans took charge. This was reduced to 75 per thousand by sanitary measures, such as boiled water, screens, disinfection, improved food, less crowding, better air, more sunlight, etc., but despite these sanitary improvements the death rate could not be hammered down below 75 per thousand. Then it was found that many of the prisoners were infected with hookworms. Thymol was administered and the death rate fell to 13.5 per thousand. Schapiro<sup>49</sup> found that treating hookworm disease on plantations in Costa Rica caused an increase in earning capacity and in acreage cultivated. On one farm, the laborers earned 27 per cent. more, and on another 14.6 per cent. more. Another farm cultivated 33 per cent. more coffee with the same number of laborers, at a lower unit cost. He also noted a reduction in morbidity and infant mortality.

Another instance of the collateral benefits resulting from sanitary work is the plague campaign in San Francisco, which cut typhoid fever in half, although no special attention whatever was paid to the latter disease. The purification of the water supply in Hamburg by filtration cut down the general death rate and diminished the morbidity of diseases not water-borne. One of the most encouraging phases of sanitary work directed against tuberculosis, typhoid fever, and hookworm disease is the assurance that a successful campaign will result in fundamental and permanent control or eradication of other communicable diseases. The prevention of tuberculosis deals especially with personal hygiene, and the prevention of typhoid fever and hookworm with the sanitation of the environment. The combination of the two, therefore, embraces almost the entire range of preventive medicine.

## CHAPTER III

### DISEASES SPREAD LARGELY THROUGH DISCHARGES FROM THE MOUTH AND NOSE

This group of diseases is the most prevalent and damaging of the infections to which flesh is heir. The respiratory diseases prevail more especially in temperate, cold and variable climates, but occur also in warm latitudes and even in the tropics. They are endemic everywhere, epidemics are frequent, and pandemics sweep the world like a devastating plague about once a generation. As a group, the respiratory infections are less well understood and hence less controllable than the intestinal diseases. In addition to the usual modes of spread by contact and through the discharges from the mouth and nose, the respiratory diseases may also be transferred in many other ways; thus, infection may be contracted in food and drink, by hand to mouth infection, or by fomites, such as cups, spoons and other things that are mouthed. Infection taken into the mouth and nose does not necessarily cause a respiratory disease, as, for example, cerebrospinal fever.

### TUBERCULOSIS

Tuberculosis is the most frequent and widespread of all the major infections. In this country 9 per cent. of all deaths, and in Germany 12 per cent., are caused by tuberculosis. The toll falls heaviest during the period of life of greatest usefulness—thus 30 per cent. of all deaths between the years of 15 and 60 are due to pulmonary tuberculosis alone. Naegeli, from a careful examination of a large number of bodies in Zurich, found evidence of tuberculosis in over 90 per cent. The lowest figures based on the evidence of pathologic anatomy are those of Beitzke, who examined 1,100 bodies in Berlin. In children under 15 he found evidence in 27.3 per cent., and in persons over 15, 58.2 per cent. The difference between Naegeli's figures and Beitzke's is due to a difference in the interpretation of the pulmonary scars and adhesions at the apices, and the small fibrous nodules in the lungs. Beitzke does not consider such lesions as of tuberculous origin, and leaves them out of his figures. If these were included, his percentage would also be very much higher. The frequency with which we become tuberculized is indicated by the

fact that 70 per cent. of persons more than 15 years old give the von Pirquet cutaneous reaction.

In the United States it is estimated that 160,000 persons die each year of tuberculosis.<sup>1</sup> Of the 100,000,000 people now living in this country, it is estimated that 9,000,000 are doomed to die of tuberculosis, unless the disease is checked. The loss in life and treasure is appalling. It costs the United States alone about \$500,000,000 annually. It is, therefore, most encouraging that preventive measures based upon modern conceptions of the disease as a communicable infection are beginning to give encouraging results.

The number of cases of clinical tuberculosis in a community may be estimated, according to Philip of Edinburgh, by multiplying the number of deaths from tuberculosis at a given time by 20. More conservative estimates in this country use 10 as a factor. Thus in 1911 there were 4,817 deaths from tuberculosis in Massachusetts, which would mean nearly 50,000 cases in the state during that year. About 1/5 of these are extrapulmonary, and about 1/5, or 10,000, need hospital or sanitarium care. Therefore, the number of deaths from tuberculosis multiplied by 2 gives an approximate estimate of the number of beds necessary to provide for the open cases. In the Framingham demonstration, Armstrong found 1 per cent. of the population had active tuberculosis, and 2.15 per cent. had active or arrested tuberculosis. From this it is estimated that in the United States at large the ratio of the known cases to deaths would be about 7 to 1 for active tuberculosis and 15 to 1 for active and arrested cases. In Cleveland, Ohio, 4.7 active cases were registered with the health department per death from tuberculosis.

Tuberculosis began to decline before the nature of the infection was known.<sup>2</sup> The decline is gradual. Modern methods have so far made little apparent impression upon the gross amount of the infection. The social and economic conditions of the mass of the population must be improved before any great decline in the mortality rate can be expected, as will presently be pointed out.

Tuberculosis is fast becoming, in fact already is, a class disease; it is more prevalent among the poor than the well-to-do. Hence the prevention of tuberculosis has become a sociologic problem. Poverty with its attendant hardships—poor food, bad housing, crowding, overwork and worry—diminishes resistance to the disease; while prosperity, which buys good food, rest, change of air and scene, choice of occupation, and diversion, increases our resistance to the disease, and avoids contact with the infection. An increase of wage or decrease in the cost of living;

<sup>1</sup> The death rate from all forms of tuberculosis in the registration area of the United States in 1917 was 146.4 per 100,000, and from tuberculosis of the lungs 128.9.

<sup>2</sup> Villamin in 1865 demonstrated by inoculation of rabbits that tuberculosis is an infectious disease; proven by Koch in 1882.

shortening the hours of work; improving the conditions of industrial hygiene; adding to the number of holidays; playgrounds, parks, and wholesome recreation, all help to increase our resistance against and diminish the prevalence of tuberculosis. Science has shown the way; it remains for society to apply the knowledge. "Social justice" is part of the program of preventive medicine.

A distinction should be drawn between *tuberculous*, which means a process due to the tubercle bacillus, and *tubercular*, which means tuberculous-like. The student should also keep in mind the difference between tuberculous *infection* and tuberculous *disease*, for only a small proportion of those infected develop clinical tuberculosis. If tuberculosis were an acute disease with a short period of incubation, its contagious nature would be as apparent as diphtheria or scarlet fever.

#### **The Difference between the Human and the Bovine Tubercle Bacilli.**

—There are at least three kinds of tubercle bacilli: human, bovine, and avian. The human and bovine varieties resemble each other closely; the essential difference lies in the fact that the human type is very pathogenic for man, but has little pathogenicity for cattle, rabbits, monkeys, and other animals. On the other hand, the bovine type is very pathogenic for almost all mammalian animals except man; it is pathogenic for man, but less so than the human bacillus. Even when large numbers of the human bacilli are injected into a calf, a general disease does not usually result; at most only a local lesion is produced. The critical test used in almost all laboratories is upon rabbits. When 0.01 milligram of a bovine culture is injected intravenously, or 10 milligrams subcutaneously, into a full-grown rabbit, generalized tuberculosis results in about 6 weeks; whereas 10 to 100 times these amounts of a human strain produce at most a slight localized tuberculosis. The culture must be young, that is, about 3 weeks old; it should be taken from solid media and weighed while moist.

The human bacillus grows luxuriantly upon culture media, covering the entire surface of the medium with a rich, dry, crinkled, mold-like vegetation. The growth of the bovine bacillus upon artificial culture media is more sparse, thinner, less extensive, and somewhat slower. According to Theobald Smith, who in 1898 pointed out the differences between these two types, the human bacillus produces in artificial culture media a different reaction curve from that produced by the bovine bacillus.

Morphologically the bovine bacillus is often shorter, plumper, and stains more uniformly than the human bacillus, which is ordinarily club-shaped, irregular, and stains with interrupted markings. The morphological and tinctorial characters are not sufficiently distinctive to distinguish one type from the other.

There are no specific differences between the tuberculins of bovine and human origin.

The *avian tubercle bacillus* is found most frequently in chickens and also in pigeons, pheasants, and guinea-fowl. Geese and ducks appear immune. The avian bacillus is quite pleomorphic and stains somewhat more readily than either the human or bovine types. The avian bacillus grows luxuriantly upon artificial culture media at 45° C. and even multiplies at temperatures as high as 50° C., which is in marked contrast to the mammalian types, which do not vegetate above 40° C. The avian bacillus grows rapidly, so that upon glycerin-agar or upon blood serum there is an abundant growth in 10 days, which consists of a white, moist, and greasy mass quite different in young cultures from the dried and crinkled appearance of the human type. Guinea-pigs show a decided resistance to the avian cultures, but rabbits are susceptible, although characteristic lesions do not develop. Chickens and pigeons may be infected with certainty by feeding, and it is probable that in nature avian tuberculosis is generally transmitted in this way.

Acid-fast bacilli are found in cold-blooded animals, and are also widely distributed in nature. They grow best at room temperature (20 to 30° C.), and are inhibited at blood heat. They are not pathogenic for warm-blooded animals. Some of these cultures are called *fish tubercle bacilli*, but their relationship to tuberculosis is doubtful.

**Bovine Tuberculosis in Man.**—Concerning bovine tuberculosis in man, we now possess definite knowledge which permits of precise statements. At one time the danger of bovine tuberculosis to man was greatly exaggerated. Koch went too far on the other side when he announced at London before the International Congress on Tuberculosis in 1901 that there was practically no danger of man contracting tuberculosis from cattle. Later Koch modified this dictum, for it was soon proved that the bovine bacillus has a certain amount of pathogenic power for man and that some of the tuberculosis in man is contracted from bovine sources. About 25 per cent. of all tuberculosis under 5 years is associated with the bovine bacillus. Fatal bovine tuberculosis is rare after the fifth year. The bovine bacillus is responsible for about 0.5 per cent. of all deaths due to tuberculosis.

Pulmonary tuberculosis in man is practically never associated with the bovine bacillus. Bovine tuberculosis in man is usually a disease of the lymph glands or bones—the lymph nodes of the cervical region and the lymph nodes in the abdomen being especially attacked. This is due to the fact that the portal of entry of the bovine bacillus is usually through the tonsils or the small intestines. Bovine tuberculosis may become a fatal infection in man when it is generalized through the blood in the form of acute miliary tuberculosis or when it localizes in the

meninges or other vital parts. About one-quarter to one-third of all cases of tuberculosis in children under 5 years of age is associated with the bovine type. It is probable that all these cases derive their infection through the ingestion of tubercle bacilli in cow's milk. There is little danger from meat, as it is usually cooked and tuberculosis of the muscles is very rare.

The following table<sup>3</sup> shows the relation between bovine and human tuberculosis in 2,527 cases:

These cases include all that have been published up to 1917, namely:

1511 cases collected by Park and Krumwiede (1912), which also include those of the British Royal Commission (1907-11), and those of Bulloch (1910).

356 cases of Eastwood and Fred Griffith (1914), (1916).

430 cases of Stanley Griffith (1914), (1915-17), (1916).

70 cases of Fraser (1912).

72 cases of Mitchell (1914), and

88 cases of Wang (1917).

2527 total cases.

COMBINED TABLE OF ALL CASES

CLASSIFICATION	Adults 16 years and over		Children 5 to 16 years		Children under 5 years	
	Human	Bovine	Human	Bovine	Human	Bovine
Pulmonary tuberculosis, including sputum .....	1000(a)	5	28	...	45	1
Abdominal tuberculosis.....	24	7(b)	13	17	29	34
Generalized tuberculosis.....	39	2	32	3	169	22(c)
Tuberculous meningitis.....	6	..	13	5	55	10(c)
Tuberculosis, genito-urinary.....	35	4	4	...	...	...
Tuberculous skin .....	12	3	4	6	2	...
Tuberculous cervical adenitis.....	62(d)	10	61(d)	76	18	75
Tuberculous axillary adenitis.....	6	..	8	...	4	...
Tuberculous bones and joints.....	82(e)	4	255(f)	61	89(g)	54(h)
Latent tuberculosis.....	2	1	2	2	4	1
Miscellaneous (other forms).....	5	2	...	1	...	2
	1273	38	420	171	415	199
Percentage of bovine infection at each age period.....	2.9		28.9		32.4	
Mixed strains reported by Park and Krumwiede.....	Total .....2,516 11					
	Grand total..2,527					

(a) Including 4 atypical strains.

(b) " 1 intermediate strain.

(c) " 1 mixed strain.

(d) " 1 atypical strain.

(e) Including 3 atypical strains.

(f) " 10 " "

(g) " 2 " "

(h) " 3 mixed strains.

<sup>3</sup> *Jour. of Path. and Bact.*, Apr., 1917, p. 131.

From a study of 1,038 of these cases we find:

16 years and over.....	686 cases	9 with bovine bacilli=	1.3%
Between 5 and 16 years....	132	“ “ “	=25.0%
Under 5 years .....	120	“ “ “	=49.1%

Many of the cases included in the above total were selected cases. The 436 cases studied in the Research Laboratory in New York, however, were not selected; of these cases the following were found associated with the bovine bacillus:

Diagnosis	Adults	Five to Sixteen	Under Five
Pulmonary tuberculosis.....	None	None	None
Tuberculous adenitis, cervical.....	4%	37%	57%
Abdominal tuberculosis.....	16%	50%	68%
Generalized tuberculosis.....	3%	40%	26%
Tubercular meningitis with or without generalized lesions.....	....	....	15%
Tuberculosis of bones and joints.....	5%	3%	....

Kossel's table also brings out the significant fact that in organs directly related to the digestive tract, like the lymph nodes of the neck and the abdominal organs, bovine bacilli are as frequent as human bacilli.

Eastwood and also Griffith<sup>4</sup> studied a series of 195 deaths from all causes, between the ages of 2 and 10 years. The results of these interesting studies are combined in the following table:

Age Periods	Number of Cases			Classification of Culture Isolated		
	Free from Tubercle Bacilli	Tubercle Bacilli Dead	Tubercle Bacilli Living	Bovine	Human	Mixed Bovine and Human
2—3 years.....	27	1	19	6	13	—
3—4 years.....	12	2	21	4	17	—
4—5 years.....	14	4	14	1	13	—
5—6 years.....	12	3	15	—	14	1
6—7 years.....	1	3	16	3	13	—
7—8 years.....	3	2	2	—	2	—
8—9 years.....	4	2	4	1	3	—
9—10 years.....	4	3	7	2	5	—
	77	20	98	17	80	1

It will be noted that of the total of 195 children, 118, or 60.5 per cent., showed evidence of tuberculous infection. The condition found in the 118 was as follows: In 92 (47.2 per cent. of 195 or 78.0 per cent. of 118) tuberculous lesions, verified by subsequent cultures, were found;

<sup>4</sup>Reports to the Local Government Board on Pub. Health and Med. Subjects. London, 1914, N. S.. 88. 1914.

in six (3.1 per cent. of 195 or 5.1 per cent. of 118) living bacilli were obtained in culture, but there were no tuberculous lesions; and in 20 (10.3 per cent. of 195 or 16.9 per cent. of 118) tuberculous lesions were present, but the tubercle bacilli apparently were dead. One of the interesting features of this investigation is that living tubercle bacilli may be present in children in the absence of lesions, and on the other hand, tuberculous lesions may be present while the bacilli responsible for them may be dead.

The more recent figures are well summarized by Griffith,<sup>5</sup> who analyzed 1,068 cases studied by the British Commission on Tuberculosis. Of this number, 803 showed human bacillus infection, 194 bovine bacillus infection, and 5 a mixed infection. Of various regions involved, the examination showed that bovine infections occurred as follows: Bones and joints, 19.7 per cent.; genito-urinary organs, 17.65 per cent.; cervical glands, 46.3 per cent.; meninges, 20 per cent.; scrofuloderma, 34.65 per cent.; lupus, 48.9 per cent. As to the age periods, bovine infection occurred as follows: during the first five years of life, 37.55 per cent.; from five to ten years, 29.45 per cent.; from ten to sixteen years, 14.66 per cent.; after sixteen, 6.25 per cent.

Woodward voices the prevailing opinion when he maintains that the more deeply we go into the subject, the bovine side of the question comes to take a larger and larger place, especially in connection with surgical and abdominal tuberculosis, not only in the child but even in the adult.

From the standpoint of our present knowledge we must consider that practically every case of bovine tuberculosis in man is ingestion tuberculosis, contracted from milk or fresh milk products. However, it may require favorable circumstances in the teeth, tonsils, intestines, or other portions of the digestive tube to permit the bacilli to penetrate. Oftentimes the bovine bacillus lodges in the glands but fails to set up disease on account of low virulence or resistance of the host. How the tubercle bacilli get into milk and the frequency with which it is infected are discussed on page 777.

Occasionally butchers and also pathologists at autopsies become infected with the bovine bacillus through wounds. These accidents furnish further experimental proof that the bovine type of the tubercle bacillus possesses a certain degree of pathogenicity for man, though in the adult it appears to be comparatively slight. Skin tuberculosis is usually benign.

<sup>5</sup> "The Bacteriological Characteristics of Tubercle Bacilli from Different Kinds of Human Tuberculosis." *Journ. of Path. and Bact.*, Feb., 1920.

## MODES OF INFECTION

There are two great sources of human tuberculosis: the principal source is man himself; the secondary source is cattle.

From man tubercle bacilli leave the body mainly in the sputum, where they are found in great numbers in all open cases of pulmonary tuberculosis. Tubercle bacilli may also leave the body in the discharges from any open tuberculous lesion wherever situated, especially in discharges from the lymphatic glands, bones, intestinal or genito-urinary tracts, or the skin. In open cases of pulmonary tuberculosis some of the sputum is swallowed and the bacilli appear in the feces, therefore any or all of the discharges from the body may be infective. But, from the practical standpoint of prevention, the bacilli in the matter brought up from the lungs are the source of the danger in the overwhelming majority of cases.

Practically all observers agree with Koch that *human sputum is the main source of human tuberculosis*. Whether the tubercle bacillus is usually transferred directly or indirectly, in moist or in dry state, by inhalation or ingestion, are questions still undetermined. The question at issue is a quantitative one; that is, how often are we infected by the direct aërogenic route, how often through the tonsils and upper respiratory passages, how often through the digestive tube, etc.?

**Aërogenic Infection—The Cornet-Koch Theory.**—The belief that tuberculosis is air-borne, that is, that pulmonary tuberculosis is a primary inhalation infection, has long been the natural and favorite theory, from the fact that the lungs are most frequently affected. This opinion was strongly expressed by Koch in 1884, and repeated by him in 1901, at the British Congress on Tuberculosis. For many years it found practically universal acceptance. Cornet taught that the tubercle bacilli entered the lungs in the dust of dried and pulverized sputum.

The evidence of pathologic anatomy strengthens the belief in the importance of aërogenic infections as the chief portal of entry. Thus, the studies by Ghon,<sup>6</sup> at the St. Anne's Children's Hospital in Vienna, indicate very strongly that the actual path of infection is by the air passages. Approximately 95 per cent. of 184 autopsies studied by him represent a primary localization of the bacilli in the lungs. On the other hand, it seems that direct aërogenic infection has been greatly overestimated, while some students of the subject go so far as to state it is of little or no practical importance. It is believed that very few bacteria suspended in the air actually reach the lungs, being caught on the moist mucous membranes of the upper air passages. Further, tuberculosis of the lungs is usually at the apex, which is not in the direct line that floating particles in the air would usually be mechanically carried. It is true

\* "Der primäre Lungenherd bei der Tuberkulose der Kinder," Berlin, 1912.

that dust under certain conditions may contain tubercle bacilli, but it is now known that this organism soon dies when exposed directly to the sun and air, and that the dust out of doors is not apt to contain many live bacilli, and when it does so the dilution must be enormous. It is different with house dust. Tubercle bacilli may live a long time in dark, moist places, but even here the danger cannot be as great as might be supposed when we study the nature of tuberculous sputum. This substance is usually tenacious and gummy, and dries into tough, glue-like masses, which are pulverized with great difficulty. It therefore seems unlikely that dust under ordinary circumstances would contain dangerous numbers of live tubercle bacilli. The danger from this source is further diminished when we consider that a large number of tubercle bacilli die in sputum even when protected from sunlight and other injurious influences. It is now known that even under most favorable conditions in artificial culture media the great majority, perhaps 99 per cent., of the bacilli die within three months. Transplants made from cultures over six months old usually do not grow. The danger of house dust containing live tubercle bacilli from a quantitative standpoint is, therefore, reduced; on the other hand, street dust raised by a March wind, or house dust raised by beating carpets or dry sweeping is a real peril.

A dusty atmosphere, even though it contains no tubercle bacilli, is, however, dangerous, in that it irritates the delicate mucous membranes and thus opens the door for infection.

One point of importance in this controversy is the experimental evidence that it requires very few tubercle bacilli by inhalation to produce the disease, whereas it may require hundreds and even thousands to cause infection by ingestion. Findel found that from 6,000 to 19,000 times as many tubercle bacilli are needed when fed as when inhaled, to produce the disease in guinea-pigs. This is given as a reason why infection via the digestive tract is comparatively rare in man.

Cornet and others have actually found live tubercle bacilli in the dust and upon objects of rooms where tuberculous patients are careless with their sputum. In one of Cornet's experiments 47 out of 48 guinea-pigs exposed to the dust produced by sweeping a carpet with a stiff broom became tuberculous. The carpet had been purposely infected with tuberculous sputum shortly before. Dust containing tubercle bacilli may also enter the atmosphere from soiled linen, upholstery, handkerchiefs, and other fabrics containing the dried tuberculous sputum. Tuberculous dust may also be stirred up by walking over floors and dragging the infection by ladies' skirts. Crawling infants and playing children are exposed to especial danger of infection. They get the fresh virulent material on their hands, which are then carried to the mouth. It is now believed that in most cases of tuberculosis the infection is contracted in childhood, but the disease develops later.

**Droplet Infection.**—When it was found that the danger from dust theoretically was not as great as was supposed, Flügge called attention to the fact that in speaking, coughing, sneezing, and in other violent expiratory efforts the fluid contents of the mouth are sprayed into the air in the form of a fine mist. These tiny droplets contain tubercle bacilli or germs of any other infection that may be in the mouth. Ordinarily these droplets are only carried 2 or 3 feet, but under exceptional circumstances may be carried 30 or 40 feet or more; however, at these distances the dilution is enormous and the danger, therefore, much diminished. The tubercle bacilli contained in the droplets sprayed from the mouth are fresh and virulent, and may land directly upon the mucous membranes of the healthy individual or may be conveyed indirectly through food, fingers, and other objects. There is danger from droplet infection, but it cannot be the usual mode of transmission in tuberculosis from the nature of the circumstances. The danger from droplet infection is increased by close association with the patient in stuffy, ill-ventilated rooms, especially if the individual does not take proper care in coughing and sneezing. For a further discussion of droplet infection see pages 461 and 940.

**Ingestion Infection.**—Little by little the view gained ground that some cases of tuberculosis, particularly in children, might be due to bacilli entering through the mucous membrane of the alimentary canal. Now we recognize that much of the tuberculosis in children comes through the alimentary tract. Many years before the discovery of the tubercle bacillus Chauveau (1868) was inclined to the belief that the alimentary canal may be the portal of entry in tuberculosis. Woodward in 1894 maintained that the infecting bacilli might reach the lungs through some part of the alimentary canal. He drew attention to the fact that in many children, and also in animals fed on tuberculous material, the lungs may be markedly affected. He traced the course of the infection through caseous or old calcareous mesenteric glands up through the diaphragm to the posterior mediastinal glands, and so to the lungs. Still in 1899 analyzed 259 fatal cases of tuberculosis occurring in the Hospital for Sick Children, London, and concluded that the infection had occurred through the alimentary canal in 20.5 per cent. of the cases. Shennan in 1900, dealing with 316 autopsies at the Royal Hospital for Sick Children in Edinburgh, found this ratio to be 28.1 per cent.

There is no doubt that the lungs are more or less involved in all cases of generalized infection, especially in children, but these are not cases of pulmonary tuberculosis (phthisis) in the usual meaning of the term. Children rarely have phthisis. It is phthisis or pulmonary tuberculosis which causes 87.5 per cent. of all the mortality from tuberculosis and whose mode of origin is now in question.

Behring in 1903 maintained that the tubercle bacilli might be taken

up from the intestine and pass through the mesenteric glands, so gaining access by the blood stream to the lungs without leaving any lesion in the gut or glands to mark the portal through which they had entered or the route by which they had traveled, and that pulmonary tuberculosis was commonly caused in this way. Behring's theory of the origin of phthisis did not find a ready acceptance. Nevertheless, the belief that phthisis may be caused by bacilli which have been swallowed and absorbed from the digestive tube gradually gained ground. Vallée in 1904 concluded from his own investigations that ingestion of dust or food infected with tubercle bacilli was the quickest and surest method of infection. A little later Calmette (1905), of Lille, appeared as a strong supporter of this view. Calmette went so far as to assert that the immense majority of cases of pulmonary tuberculosis in man are caused by ingested bacilli and not by inhalation. Whitla, in 1908, and Symmers repeated some of this work and became converted to Calmette's doctrine, and these views have gained a number of adherents. Cobbett (1910) considers that the ingestion theory is based on a slender substructure of experiments from which too sweeping conclusions have been formed. Thus Calmette and his colleagues claim that even anthracosis is caused not by the carbon particles inhaled, but the particles ingested, which pass through the intestinal mucosa and lodge in the lungs. Cobbett showed the experimental error and demonstrated that India ink intimately mixed with cream is not absorbed in any great amount from the intestine, for the cream reappears of a normal color in the lacteals. He found, however, that feeding finely divided carbon matter caused traces of pigmentation in the lung and bronchial glands when long continued. Heller and Vulcanstein showed that the feeding of large amounts of coal dust never produces that grade of anthracosis which is found after the inhalation of much smaller amounts.

There is now sufficient proof to state definitely that tubercle bacilli, when taken in food or drink, may pierce the mucous membrane of the digestive tube and produce lesions in distant parts of the body. It is also demonstrated that the tubercle bacillus may thus travel without leaving macroscopic evidence of its passage in its wake. Fraenkel<sup>7</sup> and others have shown that the tubercle bacilli may pass through the uninjured skin of guinea-pigs, leaving no trace of their passage at the place where they had been rubbed upon the skin, yet causing tuberculosis of the internal organs. Tubercle bacilli remain alive in lymph nodes, as well as other organs, for 104 days (Bartel) without producing gross or visible changes. Ravenel and others have shown that tubercle bacilli may pass through the intestinal wall without leaving a trail behind them. It does not, therefore, necessarily follow that the seat of the primary lesion in tuberculosis is the site of the entrance of the infection.

<sup>7</sup> *Hyg. Rundschau*, XX, 15, Aug. 1, 1910, p. 817.

It is also claimed that, no matter how the tubercle bacillus reaches us, whether in dust or droplets, by kissing, or through fingers, flies, cups, handkerchiefs, or milk, it either passes through the tonsils or mucous membrane of the upper respiratory passages, or is carried into the intestinal tract and absorbed from the intestines. Viewed in this light, the portal of entry even in dust infection may be through ingestion rather than through direct aërogenic infection of the lungs. Experimentally it is easy to prove that tubercle bacilli given by the mouth may produce a generalized and fatal tuberculosis; thus, of 100 guinea-pigs given one large feeding of a bovine culture by Rosenau and Anderson, 99 died of tuberculosis. That infection by ingestion does not tell the whole story is judged from the fact that primary tuberculosis of the mesenteric nodes in man is not as common as we might expect. On the other hand, it is claimed that the tubercle bacillus may pass these lymph glands, leaving little or no trace behind them. Thus the work of Weichselbaum and his pupils, Bartel, Neuman, and Spieler, strengthens the importance of ingestion as the portal of entry. These investigators found that the tubercle bacillus produces, in addition to the specific tubercles, other lesions of a simple lymphatic hyperplastic character. These early lesions are called the "lymphoid stage" ("lymphoide stadium"). The recognition of this early stage is of importance in determining the point of invasion.

These investigators assume that the tubercle bacillus is carried from the mesenteric or the neck glands either through the lymphatics directly, or through the thoracic duct and the arterial circulation to the lungs and other tissues and organs of the body. The disease usually localizes itself in the lung because this organ presents the least resistance.

Weichselbaum believes that ingestion tuberculosis occurs much more often in man than is commonly supposed, and especially in children. He assumes that the tubercle bacilli may pass through the mouth, nose, or throat. It seems immaterial whether the bacillus is taken with food or other substances placed in the mouth, or is contained in the inspired air, or enters the mouth and nose through any other medium. The first lesions do not consist in the formation of specific tubercles, but in the so-called lymphatic tuberculosis. This stage lasts a variable time and may end in recovery or may lead to specific tuberculosis either through reinfection, or it may light up itself without a new infection. The specific tubercles may occur either at the portal of entry or in the lungs and bronchial glands or in other organs.

Behring (1903) brought forward the theory that alimentary infection occurs in the early months of life. The tender mucous membrane of babies permits the bacillus to pass readily. The bacilli remain latent in the tissues and acquire increased activity later in life. According to this

view tuberculosis of adults is the "end of a song, the beginning of which for the unfortunate patient was sung in the cradle."

It is clear from the evidence at hand that pulmonary tuberculosis may arise either by inhalation or by ingestion, but it is becoming increasingly clear that in most cases the bacilli enter the body through the mouth, throat and tonsils, which are common passages for air and food. Before a final judgment can be given concerning the usual channel of entrance of the tubercle bacillus, we will need more information on the subject. There are many other things about tuberculosis that are imperfectly understood. The disease needs further study.

**Flies.**—Under certain circumstances flies may readily transfer tubercle bacilli from exposed sputum to fingers, lips, or food. This may account for an occasional case.

**Water.**—Large quantities of tuberculous sputum that escape disinfection and an additional large number of tubercle bacilli in the excreta finally reach the drinking water. Nearly all persons with tubercle bacilli in their sputum, pass some of them in their feces. The tubercle bacillus is particularly resistant to putrefactive processes, and may live a long time in water. The use of contaminated water can, therefore, not be disregarded. Lawrason Brown found tubercle bacilli in the water of the Saranac River into which sewage from a sanatorium was discharged. A study of the vital statistics of Hamburg, Lowell, and Lawrence seems to show a diminution in tuberculosis following a purification of the water supply by filtration (Mills-Reineke Phenomenon, page 1148). It is clear, however, that tuberculosis is not ordinarily a water-borne infection.

**Infection in Childhood.**—Every child has numerous opportunities to become infected. Beginning with no infection at birth, a very small proportion of infants become infected by the end of the first year, as indicated by the von Pirquet skin tuberculin test. At the age of 2 years, the percentage is 10; at 4 years, 25 to 30 per cent.; from 5 to 10 years, about 50 per cent.; and by 15 years, from 60 to 70 per cent. Pulmonary tuberculosis is rare in childhood; glandular tuberculosis common.

The infant at birth has a clean bill of health. After a year, it becomes a quadruped and on all fours, so that it comes in close contact with sputum on the floor. Soon it drinks cow's milk, much of which contains tubercle bacilli. As the child grows, it continues in close contact with raw sputum in the dust and dirt of floors, streets, gutters and surfaces, so that it soon "eats its peck of dirt." At school, at play, and at home the ingestion of offal and filth of all kinds is repeated. The contact between child and child, and between child and adult is intimate, and of such a nature as to favor the spread of infection. The child at play, at marbles, at ball, at hoop rolling, at top spinning, at rope skipping, and in scores of other ways cannot help getting on its hands the sputum of others. Children have no inherent sense of cleanliness. Hand

to mouth infection becomes a hygienic problem of first rank. Children thus have frequent chances of acquiring tubercle bacilli from dust, dirt, milk, droplets, and other sources. Krause believes that the "schmutz and schleim" infection of Volland plays a major rôle in children, and that the adult disease is an expression of childhood infection.

**Contact Infection.**—The majority of cases of tuberculosis contract the disease through "contact." Contact infection is a general and convenient term; it implies the rather quick transference of fresh infection in which the bacilli pass from one individual to the other in a brief space of time and through a short distance. Contact infection may be either direct or indirect; through dust, through bacilli in the air, or through contaminated food, through soiled fingers or objects; through sputum smeared surfaces, as well as in numerous other ways. The infections transferred through kissing, pencils, pipes, toys, cups, and other objects all come under the convenient category of "contacts." Even infection through droplets is included in the present-day conception of contact infection. The term is a practical one, and implies close association, though not necessarily actual contact, between the sick and the well. Viewed in this sense, tuberculosis is a house disease or a family disease. With this conception it makes little practical difference whether the infection enters the body through the respiratory tract or the digestive tube. Either or both would be possible in regarding the disease as "contagious" in the sense of contact infection.

Dr. H. G. Lampson in his "Studies on the Spread of Tuberculosis in Five Counties of Minnesota" <sup>8</sup> came to the conclusion that 79 per cent. of individuals fully exposed for a long period of time to open cases of tuberculosis became infected. Only 28 per cent. of those partially exposed or exposed for a short period of time became infected. The percentage of infections from casual exposure such as everyone encounters, was small, 8 per cent. The more frequent infection of children is explained, at least in part, by their more intimate contact with the patient. At all ages, the intimacy and length of exposure are the determining factors.

Pollak states that the earlier the infection the more serious the outcome. This receives support from Wallgren's statistics, for out of 51 consumptives, 15 had been exposed during the first 5 years of life, whereas of the 13 healthy persons who gave a history of exposure, in but 1 case had that exposure been before the sixth year. It is now believed that the *infection* is usually received during childhood, but remains latent until adolescence or early adult life, when the *disease* becomes clinically apparent.

Although there is some doubt concerning the exact mode of transmission and the portal of entry that the tubercle bacillus usually takes, we

<sup>8</sup> *U. S. Public Health Reports*, Vol. XXX, No. 2, Jan. 8, 1915.

have sufficient knowledge to guide our preventive measures with every assurance of success. One thing is certain: tuberculosis is an infection spread mainly from man to man, usually because sputum in some form or other enters the mouth; and secondarily from cows, through milk.

### IMMUNITY

Man possesses a considerable resistance to tuberculosis. This is shown by the fact that many cases recover spontaneously and that 70 per cent. of all individuals who reach the age of 16 years and who spend most of this time in association with their fellowmen under the usual urban conditions have at one or more times been infected. The resistance to tuberculosis increases after middle life, due perhaps to the immunity which is induced by these prior infections. The rarity of conjugal phthisis is thus explained. There is probably no true racial immunity to tuberculosis. Some races show a smaller incidence to the disease, owing probably to modes of life, habits of nutrition, and conditions of exposure. Some of the white races seem to have acquired a certain degree of resistance through inheritance (?) and almost universal infection. All races long removed from civilization are particularly susceptible.

The human body is capable of taking care of a certain amount of infection without the development of clinical tuberculosis. The dose, that is, the number of tubercle bacilli and their virulence, is, therefore, a very important factor in determining the course of events. This may readily be demonstrated upon susceptible animals and is doubtless true of man. It takes at least ten tubercle bacilli to infect a guinea-pig. Frequent reinfections occurring at short intervals with small numbers of tubercle bacilli may break down the immunity. *In man the balance between immunity and susceptibility to tuberculosis is delicately adjusted: there is a very small factor of safety.* The resistance to the infection may be increased by attention to personal hygiene, fresh air, and good food; immunity may readily be broken down by any weakening influence; herein lies the keynote of personal prophylaxis.

The immunity to tuberculosis is not sufficiently strong to overcome a large amount of infection. As in all other infectious processes, the strongest and most robust individuals in the prime of life succumb to the disease in a short time if they receive into the tissues a large number of virulent tubercle bacilli. Hence the avoidance of the infection is one of the most important of our preventive measures.

Romer has shown that active tuberculous guinea-pigs resist a second small dose of tubercle bacilli. Krause confirmed these results on monkeys, and von Behring and Calmette on cattle. This indicates that a disease which is progressive within the body may ward off fresh infection from without. Superinfections may, however, occur under certain

conditions. Krause believes that tuberculous infection can occur once only during the life of man, and this usually takes place in childhood.

The frequency with which such diseases as measles, whooping cough, syphilis, typhoid fever and other infections are followed by tuberculosis makes us believe that most acute infectious processes diminish resistance to the tubercle bacillus. Syphilis predisposes to tuberculosis. A high percentage of adult consumptives give a positive Wassermann reaction.<sup>9</sup>

The mechanism of the immunity to tuberculosis is probably exceedingly complex. There is no antitoxic immunity. The tuberculins are not true toxins. Phagocytosis and cellular reactions play a very important rôle. Studies upon anaphylaxis throw a certain amount of light upon the mechanism of immunity in tuberculosis. The phenomenon of hypersusceptibility is beautifully illustrated in the action of tuberculin, which is a comparatively harmless substance to a normal individual, but produces a marked reaction in a sensitized individual. This reaction must be useful in protecting the body against the invasion of the tubercle bacillus, and also in guarding it against the spread of the disease after it has become localized. Thus, if tuberculin is placed upon a normal conjunctiva no reaction follows.<sup>10</sup> This first application, however, sensitizes the tissues of the conjunctiva so that, if the application is repeated after the lapse of a few weeks, there is a violent reaction. The same phenomenon doubtless occurs when a tubercle bacillus lodges in a lymph gland or in the lung or some other part of the body. The first time it meets with little resistance; the next time the tissues react immediately and vigorously. All of nature's protecting agencies, such as the germicidal substances in the blood, the phagocytic cells, and antibodies, are concentrated upon the point where they are most needed. In the same way the body protects itself against the extension of a tuberculous focus. The parts surrounding a tubercle become sensitized and react so as to encapsulate the focus with a cellular and fibrous coat of mail. This reaction is probably stimulated by small amounts of tuberculin produced within the tuberculous focus. When the tuberculin is not produced autogenously in sufficient amounts, as in chronic lesions of the bones, or inactive processes of the glands or skin, the specific reaction may be stimulated to advantage by the injection of small quantities of tuberculin. If, however, the tuberculin is given in too large amounts or too frequently, the power of reaction is readily broken down.<sup>11</sup> When this occurs the mechanism of immunity has been destroyed, there is little resistance left to the extension of the infection, and death soon occurs. Clinical experience has demonstrated the danger of large doses of tuberculin or small amounts too often repeated in tuberculosis. The same may readily

<sup>9</sup> See pages 59, 65, 581; also *J. A. M. A.*, April 27, 1918, p. 1211.

<sup>10</sup> Rosenau and Anderson, *J. A. M. A.*, Vol. I, March 28, 1908, p. 961.

<sup>11</sup> A state of anti-anaphylaxis is produced.

be demonstrated experimentally in the lower animals. These facts are of fundamental importance in the use of tuberculin both in diagnosis and therapy.

It is quite proper to deny dogmatically the hereditary transmission of tuberculosis in educational pamphlets for popular use. The infection is not transmitted hereditarily, although it occasionally passes from mother to fetus congenitally. Tubercle bacilli do not occur in the spermatozoön, and do not appear in the seminal fluid. They are not found in the ovum; in fact, a tubercle bacillus in the ovum would doubtless result in the death of the egg. The bacilli, however, may pass from mother to fetus through the placenta. Warthin shows that placental tuberculosis is more common than is supposed. The lesions in the placenta are not those of typical tubercle formation.

While the tubercle bacillus itself is rarely transmitted from parent to fetus, an hereditary tendency or disposition to the disease may be transmitted. We have no definite knowledge as to what this decreased resistance consists in; it may be a diminished power of reaction. For this view there is analogy in the experiments upon anaphylaxis in guinea-pigs, in which it has been shown that hypersusceptibility to a foreign protein such as tuberculin may be transmitted from mother to young.

A mild infection with bovine tuberculosis in early life seems to leave a certain degree of immunity against the human strain. At least, persons who have glandular tuberculosis of the bovine type in childhood are said to be less apt to have tuberculosis of the lungs in later life. Likewise, the human strain injected into cattle produces a definite immunity against the bovine type. Cattle may be immunized by the intravenous injection of 2 c. c. of a suspension of a pure culture of the human tubercle bacillus. This produces an immunity which probably lasts for 1 to 2 years. It should be remembered that the human bacillus under these circumstances remains alive for a very long time, and may appear in the milk provided there is a lesion in the udder. This presents a danger which cannot be disregarded.

Trudeau long ago showed that the only definite immunity that could be induced in experimental animals was through the use of live tubercle bacilli. Webb and Williams<sup>12</sup> have produced a certain amount of immunity in guinea-pigs and monkeys by the injection of small numbers of live tubercle bacilli. This procedure is not practical, even hazardous.

Calmette and Guérin have recently reported striking results on immunity to tuberculosis in cattle, produced by vaccination with tubercle bacilli of the bovine type, reduced in virulence by prolonged cultivation

<sup>12</sup> "Immunity in Tuberculosis," *J. A. M. A.*, Oct. 28, 1911. Vol. LVII, No. 18, p. 1431. Trans. 6th Int. Cong. on Tuberculosis, 1908, 210; also, Lieb, *Journ. Med. Res.*, 1910, XXX, 3; also, Lawrason Brown, Heise, and Petroff, *Journ. Med. Res.*, July, 1914.

in media containing bile. These authors in 1911<sup>13</sup> showed that guinea pigs, monkeys and cattle could tolerate large doses of tubercle bacilli attenuated by this method without acquiring generalized disease, at the same time developing a pronounced immunity to subsequent virulent infection by the intravenous route. In a series just reported,<sup>14</sup> cattle vaccinated with attenuated bacilli showed an immunity of 18 months' duration to the most intense exposure.

The injection of dead tubercle bacilli and their products long ago proved valueless. The injection of small doses of virulent bacilli has more than once proved dangerous. The work of Calmette and Guérin points in the right direction, for there is abundant evidence for the dictum of Krause that infection is a *sine qua non* of immunity in tuberculosis: "No resistance without tubercle." It appears that immunity to tuberculosis is not general, but quite specific.

### RESISTANCE OF THE VIRUS

We have no easy method of determining just when the tubercle bacillus dies. The criterion of death depends upon animal experimentation. The tubercle bacillus has no spore and may be classed with other non-spore-bearing organisms so far as its viability is concerned. Its virulence fades before it dies. It is doubtful whether the waxy substances protect the bacillus against external harmful influences to any unusual extent. The thermal death point is 60° C. for 20 minutes. This is much less than was once considered.<sup>15</sup> Failure to recognize the lesions produced by the dead tubercle bacillus is responsible for some of the false conclusions reached by experimenters upon this subject.

From a practical standpoint the resistance of the tubercle bacillus in sputum is of prime importance. Protected from the sunlight, it is now known that they may live in dried sputum for months. All the bacilli do not survive under these conditions, but we lack methods to determine the quantitative reduction.

The tubercle bacillus withstands cold very well. It has a marked resistance against putrefactive processes. It will live a year in water, which is a fact not to be neglected, as many tubercle bacilli finally find their way into drinking water, and occasional trouble from this source is possible.

For the destruction of the bacilli in sputum only very strong germicides or exposure to steam or boiling water should be depended upon. Burning is the most practical method for disposing of tuberculous sputum (see page 1434). Five per cent. carbolic acid is sufficient, pro-

vided equal parts of sputum and solution are mixed and the exposure continued for 24 hours.

Sunlight is one of the best germicides and often destroys tubercle bacilli quickly. In direct sunlight the naked bacilli exposed directly die in a few hours; in diffused sunlight, in a few days. Tubercle bacilli imbedded in sputum masses may be protected against the germicidal action of the sun's rays. The time the bacilli may live under these circumstances is variable.<sup>16</sup>

### PREVENTION

Preventive measures are based upon two important facts: that tuberculosis is an infection mainly spread from man to man through tuberculous sputum, and secondarily from cattle through infected milk. Preventive measures fall into two categories: (1) avoiding the infection, and (2) increasing resistance through personal hygiene. Both are necessary. The infection may be avoided through segregation; the use of pasteurized milk, or milk from tuberculin-tested cattle; education; disinfection; proper disposal of tuberculous sputum; the avoidance of contact with open cases, especially with those who do not use proper precautions; early diagnosis, etc. Increased resistance may be gained through fresh air, good food, rest, and compliance with the dictates of personal hygiene. This part of the subject includes sociologic and economic reforms, without which the warfare against tuberculosis cannot succeed. Improvement in housing conditions, lowering of the cost of living, increase in the scale of wages, and all forms of uplift help secondarily to diminish the amount of the disease. Furthermore, it will be necessary to consider secondary agencies, as preventive clinics, health insurance, notification, open-air schools, day and night camps, etc.

It is well to remember that tuberculosis has gradually declined in England and also in Massachusetts since 1850—before the tubercle bacillus was discovered. The decline was gradual from 1850-1885, but quite pronounced since that date. (See Fig. 16.)

The causes of this decline have been much discussed. It may be due to better food supply at all seasons of the year, brought about by improved methods of transportation, and the general use of refrigeration and canning; it may be due to amelioration of social and domestic life; it may be due to better hygiene and sanitation; or, it may be due in part to the special antituberculosis measures. On the other hand, the decline may have been little influenced by any of the usually assigned causes, but may simply be a biological phenomenon indicating a falling off in the virulence of the tubercle bacillus, or, what seems less likely, an increased

<sup>16</sup> Von Bergen, *Schweizerische med. Wochenschr.*, Dec. 2, 1920, L, No. 49, p. 1120; also, Técon, *Paris Med.*, Jan. 3, 1920, X, 33.

resistance owing to specific immunization of the population. During recent years, there has clearly been a lessened mortality, but apparently an increased morbidity. In other words, the infection seems to be more prevalent, but the disease less fatal.

**Segregation—Sanatoria.**—Tuberculosis is a “contagious” disease, and it is now perfectly plain that one of the most important single preventive measures in this as in all other communicable diseases consists in isolation. A case isolated is a case neutralized, hence the great value to the

FIG. 16.—SHOWING THE DECLINE IN THE DEATH-RATE FROM TUBERCULOSIS. The decline is general from 1850 until 1882, when the tubercle bacillus was discovered, since which time the decline is sharper. Since 1910, the curve shows a tendency to stabilize.

community of sanatorium treatment. Isolation in this case refers only to those individuals having tubercle bacilli in their sputum. It should not be used as a terminal measure. Too often the door is locked after the damage is done. The power of forcible removal and isolation of the irresponsible, careless or indigent consumptive is essential to success. The isolation in tuberculosis need not go to the extreme practiced in the acute communicable fevers. In fact, we cannot for many years to come object to giving a case of open pulmonary tuberculosis restricted liberty, provided he is careful and cleanly and uses proper precautions in the disposal of his expectoration. When the disease

becomes less prevalent, more stringent and arbitrary measures may then be enforced.

Special measures must be taken to protect infants and children against the infection.

"Every case of tuberculosis isolated means an average of at least three less new infections." Sanatoria should, therefore, be attractive and as cheap as it is possible to run them. Free hospital care for the open cases is necessary, especially for the poor. Tuberculosis has diminished most in those countries where sanatoria are most in use.

Separate sanatoria<sup>17</sup> should be provided for the incipient cases and for the advanced cases. A sharp division is not always possible, for an incipient case may develop into an open case within a week, and, on the other hand, open cases may return to latency in a short time. It is better for each locality to have its own sanatorium than to provide large institutions which become unwieldy. Furthermore, tuberculosis, like other widespread infections, is largely a local problem. A distant sanatorium will neither attract, nor keep the chronic cases. Persons with tuberculosis need not necessarily go to a sanatorium with the object of remaining until cured. It is worth while if they go there but for a few months to learn the methods of treatment and the technic of prevention. While sanatoria should be well built and comfortable, extravagance is not necessary. Special police power to restrain the incorrigible consumptive in special detention wards or places is desirable.

**Tuberculosis Dispensaries.**—Every community should be provided with a dispensary for diagnosis, treatment, and for teaching the consumptive how to care for himself at home. Each dispensary should have at least one physician and a nurse with special experience in the problem. Much social service work can be done from such a dispensary, especially in following up cases after leaving the sanatorium. Dispensaries are necessary for early diagnosis,—one of the essentials for treatment and prevention.

**Anti-Tuberculosis Associations.**—Associations for the cure and relief of tuberculosis are essential parts of the problem, and such associations should be active in every community in order to obtain hospital accommodations for the advanced cases, sanatorium treatment for the hopeful

<sup>17</sup> Dr. Edward Trudeau went to Saranac in 1873 as a hopeless victim of consumption. All his friends were filled with horror at the idea of his going practically alone to die, as they believed, in the Adirondack wilderness, in a little town consisting of little more than a sawmill and half a dozen cabins, forty-two miles from a railroad. Dr. Trudeau did not die, however, during the winter of 1873, but grew very much better; and some ten years later, as a result of his experience, he founded the Adirondack Cottage Sanatorium, which in its primitive form consisted of a single house in which, with great difficulty, he persuaded two consumptive patients to live. That was the beginning of the demonstration in this country of the fresh-air treatment of tuberculosis, which Brehmer and others had introduced on the other side of the water. (Winslow.) Read Trudeau's inspiring autobiography.

cases, and advice for the incipient cases, to obtain and maintain dispensaries, district nursing and necessary legislation and help in the problem of education.

**Personal Prophylaxis.**—Personal prophylaxis consists in avoiding the infection and in obeying all the dictates of personal hygiene—that is, living a clean, normal, and temperate life.

Close association with persons known to have tubercle bacilli in their sputum is hazardous. This becomes especially dangerous when the contact is prolonged and intimate, such as working in the same room, especially if it is small and ill-ventilated, or living in the same house, sleeping in the same bed. The more intimate the association and the less care the tuberculous individual takes with the expectoration, the greater is the hazard. The danger diminishes somewhat with age; infants and children need special protection. The infection may further be avoided by refusing to drink from common cups, by taking care in placing objects in the mouth that do not belong there, by avoiding dusty atmosphere, and refusing to drink milk that does not come from tuberculin-tested cattle unless it is pasteurized.

Mechanical obstructions to breathing should be corrected, by surgical methods if necessary. Functional lack of proportion in the chest and lungs of young people favor infection, and every effort should be made to help the child to outgrow them. Breathing exercises and outdoor play are especially useful.

A generous diet is one of the best prophylactics against tuberculosis. Good nutrition is fundamental both in the prevention and cure of tuberculosis.

Resistance to the disease is increased by rest, fresh air, good food, sunshine, the avoidance of all depressing influences, such as worry, overwork, strain, intemperance, and excesses of all kinds. Attention should be given to slight colds and other conditions known to be predisposing causes to the disease. Tuberculosis is the one disease in which the measures of treatment and of prevention are to a large extent identical.

Conditions favoring tuberculosis are anemia and underweight, continuous overfatigue, recurrent colds, especially recurrent bronchitis, slow recuperation from any acute infection, whether influenza, measles or whooping-cough, prolonged septic processes, or typhoid fever. Syphilis is one of the predisposing causes of tuberculosis. It is well to remember that maturity of tissues, freedom from trauma, normal nutrition, and the absence of intercurrent disease or toxic influences are the important “factors of safety” on the part of the body.

Personal prophylaxis becomes the keynote of prevention when we recall that most of us become infected during childhood. It is, therefore, our problem to live so that the disease will not break out in adult life.

**Education.**—The prevention of tuberculosis, like all other widespread infections, depends for its success upon the education of the people. We are now in possession of sufficient information of a precise nature to place the facts in plain words before the public. This has been done in numerous excellent pamphlets<sup>18</sup> and popular articles in the daily press and magazines, through lectures, conferences, moving pictures, exhibits, and meetings, so that there is now a widespread understanding of the problem. The modern message in tuberculosis has been one of hope, in that the disease is curable; and one of fear, in that it is transmissible. The former has been a great encouragement and has added strength to the movement; the latter is also helpful, although it has run to extremes in some quarters. An unwarranted fear of tuberculosis (phthisiophobia) has subjected the tuberculous individual to severe hardships by branding him as a leper. Even cured cases of the disease may find difficulty in obtaining work. A wholesome regard for the infection is useful and helpful in preventive medicine, but an hysterical fear of tuberculosis is quite as unwarranted as a total disregard for the infection.

**Notification.**—Tuberculosis should be included among the list of diseases requiring compulsory notification. Without this important feature an adequate control of the disease cannot be effected. The objection to compulsory notification is based largely upon sympathy with the large number of individuals affected and the sensitiveness of the afflicted. Compulsory notification may occasionally result in individual harm, but is necessary for the communal good. The prejudice against notification in tuberculosis is rapidly being worn down, and successful reporting is part of the program of all up-to-date health administrators.

Tuberculosis is required to be reported in Maine, Michigan, Massachusetts (since 1907); many cities: Alameda, California; Asbury Park, N. J.; Boston, Buffalo, Cincinnati, New York, Salt Lake City, Trenton, Yonkers—also in Washington, D. C., Minneapolis, San Francisco, and Syracuse. The list is growing and the returns are gradually improving.

In England and Wales the notification of all forms of tuberculosis, whether in public or private practice, is obligatory, since Feb. 1, 1913. The information thus received is held as confidential.

**Disposal of the Sputum.**—As the tuberculous sputum is the principal source of the infection, it should be disinfected or disposed of so that it will be harmless to others. Perhaps the best way is to receive the expectorated matter into cloths, which may be burned, or the material may be received into one of the various forms of sputum cups and finally burned or disinfected. Persons with pulmonary tuberculosis must be warned against the possible danger to others of coughing without holding the handkerchief before the mouth and nose; under no circumstances should they spit upon the floor. Penalty for spitting upon the sidewalk.

<sup>18</sup> International Prize Essay, by Knopf. Published by *The Survey*, New York.

upon the floor of public buildings, and in street cars serves a useful purpose in diminishing the spread of tuberculosis as well as other diseases. See Disinfection of Sputum, page 1434.

**Disinfection.**—Rooms occupied by tuberculous individuals should be kept clean and disinfected from time to time. A thorough disinfection and cleansing should also be practiced before such rooms are occupied by other persons. This may be accomplished by washing all surfaces with hot soap and soda, followed by mopping with the usual solutions of bichlorid of mercury or one of the coal-tar preparations, and then a thorough airing and sunning. Formaldehyd gas alone cannot be depended upon because it lacks the power of penetration. The room may finally be renovated and refurnished. All fabrics, handkerchiefs, bed and body linen should be boiled or steamed.

**Early Diagnosis.**—Early diagnosis plays an important rôle in successful prevention; not only does it give the individual the best chances of cure, but at the same time it assures the possibility of maximum protection to others. Through the use of X-rays, tuberculin and other refinements of clinical methods it is now possible to diagnose tuberculosis at a stage when it was formerly not suspected. It is a great mistake, from the standpoint of prevention, to wait until tubercle bacilli appear in the sputum before making a diagnosis of tuberculosis. The symptoms that suggest incipient tuberculosis are rather general in character. It is often necessary to make a diagnosis by exclusion, for it may be impossible for the clinician to state just where the process is located. The symptoms that suggest incipient tuberculosis are loss of weight, rise of temperature in the afternoon, or subnormal temperature with rapid pulse, loss of appetite, languor and lack of energy, anemia, dyspepsia, with or without a cough. Probably many cases of "a slight run-down condition," of transient and irregular febrile attacks, are due to a small focus of tuberculosis hidden from the ken of the clinician. In such cases a course of rest, fresh air, and better food, with a change of scene, may often prevent irreparable damage. The establishment of preventive clinics to look after such cases and the maintenance of medical clinics to diagnose and care for the early cases are important adjuncts to preventive measures.

**Housing Conditions.**—It has long been realized, even before the reasons were understood, that the incidence to tuberculosis diminishes with improvement in housing conditions. This is a common observation in the stabling of cattle as well as the domicile of man. The reasons for this are complex. In addition to raising the standard of living, better houses lessen the chances of contact infection, afford better air and more sunshine, and tend generally to the well-being and uplift of mankind. House infection is after all another name for contact infection. Better housing helps to lessen the opportunity for the infection to develop into

the disease. Municipalities do well to enact and enforce stringent laws regulating the construction of houses, offices, stores, and workshops. The congested and squalid slums are both a disgrace and a menace. Germs are social climbers, and many a palace is invaded with an infection from a nearby neglected alley. Philanthropists cannot do better than assist in improving the housing conditions of the poor and thus help the art of hygienic living. See page 1337.

**Care of the Cases in the Home.**—Open cases of tuberculosis should not be cared for in the home, but in case they are, such homes should be visited by a public health nurse.<sup>19</sup> Home visitation is a simple but very powerful means of attacking this and other diseases. It is the surest way of reaching the indifferent and ignorant portion of the public which constitutes the great obstacle in the successful prevention of disease. Home visitation is not merely applicable, but almost indispensable in many public health problems, and should become one of the routine methods of a good public health organization. Such a system recognizes the fact that tuberculosis is not merely a bacterial invasion, but a disease of defective civilization. Through this means social relief may teach better standards of living and provide better food, light, air, housing, clothing, and occupation. A study of tuberculosis at close range has taught the lesson of the absolute necessity for individualizing the treatment of each case in order to obtain satisfactory results.

**Industrial Conditions.**—Cornet taught that many a case of tuberculosis is contracted by those who are required to work alongside of a fellow workman who has pulmonary tuberculosis, especially in crowded, poorly ventilated and insanitary workshops. We now believe, however, that most cases are infected during childhood; nevertheless, exposure at any period of life may be hazardous. Mr. Allen Joslin helped to suppress the disease within two years at Oxford, Mass., where tuberculosis was unduly prevalent, through medical inspection, aided by a nurse; removing the sick to sanatoria, and by a general improvement in the sanitary and hygienic conditions of the mill. Similar measures have been met with signal success in other industrial centers. Much real good can be accomplished along these lines.

**Tuberculosis in Children.**—In one sense tuberculosis is an infection of childhood, for about 70 per cent. of all children by the time they reach sixteen years of age react to tuberculin, thus indicating that they have become sensitized or "tuberculized." The hazard to a child living in a house with an open case of consumption is very great. One of the fundamental considerations is to separate babies at once from such an environment. Children rarely have tuberculosis of the lungs (consumption); when they do it is usually rapidly fatal. It is hazardous

<sup>19</sup> That is, a nurse specially qualified in the tuberculosis problem, and with social service instinct and training.

to permit such children in schoolrooms or even to remain at home; they should be cared for in sanatoria. It is the anemic, incipient, pretubercular, glandular, or scrofulous type that demands especial attention. Such children are best cared for in school-hospitals, sometimes called open-air schools. These children are going to furnish a large percentage of the open pulmonary cases in later life. In a school-hospital emphasis should be laid on treatment, and the teaching given secondary consideration. See page 1337.

**Bovine Tuberculosis.**—The prevention of bovine tuberculosis consists simply in using milk, cream, and fresh milk products from tuberculin-tested cattle. The cattle should be tested frequently, at least twice a year, for the disease may develop in the cow in a few months. When milk from non-tested cattle is used, it should be pasteurized, and the same precaution applies to the milk used for making cream, butter, ice-cream, and other fresh milk products.

**Directions for Testing Cattle with Tuberculin.**—Three tests are now used: (A) the subcutaneous test; (B) the intradermic test; and (C) the ophthalmic test. The *subcutaneous* test is carried out as follows:

1. Stable cattle under usual conditions and among usual surroundings, feeding and watering in the customary manner.

2. Make a physical examination of each animal, and give to each one some designation by which the animal will be known throughout the test.

3. Take each animal's temperature at least three times at two or three hour intervals on the day of injection; for instance, at 2, 5, and 8 p.m.

4. At 8 or 10 p.m. inject a dose of tuberculin under the skin in the region of the shoulder, using a sterile hypodermic syringe after disinfecting the skin at the seat of injection with a 5 per cent. solution of carbolic acid or a similar antiseptic solution.

5. Tuberculin is not always concentrated to the same degree, and therefore the dose, which should always appear on the label, varies considerably. The dose of imported tuberculin is .25 c. c. for an adult cow, and before injection is diluted with sterile water to 2 c. c. The tuberculin made by the Bureau of Animal Industry is prepared so that it will not be necessary to dilute it, and the dose is 2 c. c. for an adult animal. Yearlings and 2 year olds, according to size, should receive from 1 to 1.5 c. c., while bulls and very large animals may receive 3 c. c.

6. At 6 a.m. on the day following the injection of tuberculin commence taking temperatures, and continue every two or three hours until the twentieth hour after injection, at which time if there is no tendency for the temperature to rise the test may cease.

7. A rise of 2° F. or more above the maximum temperature observed on the previous day, providing the temperature after injection exceeds

103.8° F., should be regarded as an indication of tuberculosis. Those cases which approximate but do not reach this standard should be considered as suspicious and held for a retest six weeks later, giving double the original dose.

The *intradermic* test consists of injecting one cubic centimeter of undiluted tuberculin into the skin of the caudal fold at the root of the tail. It is therefore called the tail test. When positive, a swelling appears which persists, and should be read in about 72 hours. This test requires good technic. It is becoming popular because it is easier to interpret than the subcutaneous test, and is sometimes positive when the latter is negative.

The *ophthalmic* test consists in placing a tablet containing tuberculin in the conjunctival sac. Susceptible animals show a distinct reaction, consisting of injection, swelling and exudation.

Each of the three tests has limitations. It is often desirable to use two, or all three in special cases.

**The Bang Method of Suppressing Bovine Tuberculosis.**—More work has been done in Denmark in accordance with the recommendations of Bang in the suppression of tuberculosis of cattle, and the results achieved are of greater value than in any other part of the world. The system, in short, is as follows: Herds are tested with tuberculin upon the application of the owner of the cattle. After the test, the herd is divided into two parts, (1) the healthy section and (2) the reacting or tuberculous section. These herds are, if possible, kept in separate buildings. If this cannot be done, they are kept in separate parts of the same building, a tight partition separating them. The milk from both sections is used by the creameries, but it is the almost universal practice in Denmark to pasteurize the cream preparatory to ripening it for churning, and the law requires that skim milk shall be heated to a point that will kill the tubercle bacilli before it is returned to the farmers to be used for feeding purposes. The law further provides that the sediment that remains in the separator shall be burned.

The calves from the cows in the reacting sections are removed from their dams immediately after birth and are reared on the milk of healthy cows or on milk of reactors that has been heated. These calves are tested when they are three or four months old, and if they do not react, they are permitted to enter the sound section of the herd. As a matter of fact, reactors are very rare among these calves. Most of them are born healthy, and when cared for as directed, they remain free from tuberculosis. All cows with tuberculosis of the udder are required to be reported and are killed. Some compensation is allowed for them. The appraisement is equivalent to one-fourth of the meat value of the animal. The other tuberculous cattle in the reacting section are examined physically from time to time and killed in public abattoirs under veterinary control.

Their flesh is then disposed of in accordance with the recommendation of the inspector. Some of it is seized and destroyed, some of it is sold for food. The law further provides that cattle brought into Denmark shall be kept in quarantine until tested with tuberculin and found free from tuberculosis.

Many herds have been tested in Denmark with negative results, proving that tuberculosis is not a necessary disease among highly developed dairy cattle, and that the tubercle bacilli are not omnipresent.

**Health Insurance.**—Health insurance, sick benefits, pensions, non-employment insurance, and similar schemes to attempt social justice are helpful in the fight against tuberculosis. The German industrial associations were under government supervision and did more than care for the tuberculous workman. The heavy drains upon the funds of the industrial associations were checked by the establishment of "präventoria." These are attractive country places where the working man can go when he is "run down." This simple measure is a great boon, and prevents the development of many a case of tuberculosis as well as other diseases. See also page 1291.

**Organizing a Local Tuberculosis Campaign.**—Tuberculosis being a local problem should be attacked by every town throughout the country. The method of organizing a tuberculosis campaign is first to interest a number of different agencies, such as the church, business, doctors, politicians, women's clubs, the press, and the board of health. This beginning can best be done by one person who will devote himself or herself to the work. After the press has printed a few articles on tuberculosis and the pulpit has helped to emphasize the importance of the movement, a local committee should then be formed to invite a tuberculosis exhibit. These exhibits may be obtained either from the National Association for Tuberculosis, or from most of the state boards of health. It will require at least one hundred and fifty dollars to finance such an exhibit. A tuberculosis society should then be formed. The next step is to establish a dispensary with a physician and a nurse. An efficient nurse with social service training is essential for the success of the movement. After this is well under way, a day camp should be started in a modest way at a convenient locality, and, should this succeed, a night camp may be added. A day and a night camp is the equivalent of a local sanatorium. This much can be done by voluntary efforts and private subscription, but at this point the authorities should take over the work.

**Collateral Benefits.**—The collateral benefits of a tuberculosis campaign may be even greater than the effects upon the actual control of the disease. Even if the measures used prevent only a few cases of tuberculosis, they still would be worth while, for they preach the gospel of hygiene. The problem of tuberculosis is closely interwoven with everything that pertains to human welfare.

**Outlook.**—The control of tuberculosis is complex and difficult. Many of the factors are not understood. The prevention of tuberculosis is no longer solely a medical problem but largely a sociological problem. It is a disease of defective society. Its eradication will, however, take time on account of the chronic nature of the disease and its widespread prevalence. We should be satisfied if we diminish the amount of tuberculosis appreciably in a generation. The momentum thus gained will increase rapidly. The time will come when the comparatively few cases left may be treated by compulsory isolation or other aggressive measures. Persistence along the lines now understood will in time control the disease, which will be the crowning achievement in preventive medicine.

### DIPHTHERIA

Our knowledge of diphtheria is most satisfactory in that we know the cause of the disease and its modes of transmission; we are able to check its spread, and possess a specific preventive and curative agent of great potency.

Diphtheria spreads slowly from person to person and from community to community. It is not necessary to consider it endemic in special indigenous foci, because it is never completely absent in any large community. Newsholme points out that diphtheria epidemics and pandemics occur cyclically. The intervals between the years of epidemic prevalence vary greatly. The large American cities formerly suffered severely.

In Boston diphtheria was epidemic in 1863-64, 1875-76, 1880-81, 1889-90, and 1894; in New York in 1876-78, 1880-82, 1886-88, and 1893-94; in Chicago in 1860-65, 1869-70, 1876-79-81, 1886-87, and 1890. Within recent years such epidemic outbreaks have not taken place, and the disease should never again be allowed to get out of hand. The death rate in the United States in 1917 was 16.5 per 100,000. Diphtheria in Massachusetts in 1919 was responsible for 14.9 deaths per 100,000; or a total of 591 deaths out of 7,926 cases reported in the state.

The cause of epidemic outbursts is doubtless due to a fortuitous combination of such circumstances as a new crop of susceptible children, a particularly virulent strain of the bacillus, opportunity for contact, and similar factors favoring the spread of the infection. On the other hand, external conditions, such as dryness, may be important, for Newsholme states that "diphtheria only becomes epidemic in years in which the rainfall is deficient. There is no instance of a succession of wet years in which diphtheria was epidemic." It is more than likely that the great outbreaks are due to a combination of the three factors (1) man, (2) the bacillus, and (3) the environment. Just as a spark in a forest may cause a brush fire or a conflagration, depending upon the amount of plant growth, its distribution, its condition as to dryness, the direction and force of the wind, the topography and nature of the soil, and many other conditions, so diphtheria and other infections will smolder or burst into flame, depending upon similar factors.

Outbreaks in congested centers, schools, camps, on board ships, and in other crowded places, are common. Widespread epidemics have occurred in country districts. Washington died of diphtheria. In the tropics diphtheria is not a serious disease. It prevails especially in the temperate zones. Newsholme pointed out that it is more of a continental than an insular disease. The fatality from diphtheria has been greatly lowered since 1894, owing to the use of antitoxin and to refinements of diagnosis, as a result of which many mild cases are now included that were formerly omitted from the statistical records. Whether or not there has been a natural tendency for the disease to become milder in recent years cannot be stated.

Diphtheria reaches its maximum prevalence in the autumn of each year, which corresponds to the seasonal prevalence of scarlet fever. Diphtheria is a cold weather disease. The influence of climate is confirmed by its rare incidence in the tropics. While the seasonal prevalence is in the colder months, an epidemic once established may go on regardless of season, reaching its maximum at the period of highest temperature.

In 1878 Dr. Thrushfield published papers illustrating the way in which diphtheria hung about damp houses. A damp dwelling favors

sore throats and colds, and may thus open a way for invasion of the bacilli, just as any depressing influence may predispose to the infection. Children with scarlet fever or measles are especially prone to take diphtheria if the infection is around. Any abnormal condition of the mucous membrane of the throat and nose favors the localization of the diphtheria bacillus, and may thus act as a predisposing cause; therefore, sore throat, foreign bodies, adenoids, as well as dust or any irritant, may predispose to the disease if the diphtheria bacillus is present. Formerly, imperfect drains and sewer gas were given as the causes of diphtheria; this is a fetish which dies hard.

Studies with the Schick reaction plainly indicate that two main conditions determine diphtheria: (1) a virulent strain of the bacillus; and (2) susceptibility.

**Modes of Transmission.**—The diphtheria bacillus enters by the mouth or nose, and the lesions are usually localized in the mucous membranes of the throat, nose, larynx, or upper respiratory tract. The bacillus leaves the body in the discharges from the mouth and nose. Diphtheria occasionally affects other mucous membranes or abraded surfaces, such as the conjunctiva or vaginal mucous membrane, or open wounds; the discharges from these lesions containing the infective agent.

The bacillus may be transmitted directly from one person to another, as by kissing; or exposure to droplet infection in coughing, speaking, sneezing. The infection may be conveyed indirectly from one person to another in many ways; most common among children, perhaps, are toys, slate pencils, food, fingers, spoons, cups, handkerchiefs, or other objects that have been mouthed first by the infected child and then by the susceptible child. Experience points clearly to the conclusion that diphtheria is transmitted usually by a direct exchange of the flora of the nose and throat, rather than indirectly through inanimate objects. Bacillus carriers play a large rôle in spreading the infection. Milk may become infected and transmit the disease. The diphtheria bacillus is frail and soon dies when dried or exposed to sunlight, therefore air-borne infection is probable only in the case of close association, that is, within a few feet of the infected person and within the radius of the possibility of droplet infection.

Experience clearly teaches that diphtheria is spread mainly by the active cases; recent convalescents; mild and missed cases; and carriers.

The following description by Chapin illustrates how diphtheria and all other infections contained in the secretions from the mouth and nose may be transmitted; it also emphasizes the importance of education in personal hygiene based upon habits of biological cleanliness:

“Not only is the saliva made use of for a great variety of purposes, and numberless articles are for one reason or another placed in the mouth, but, for no reason whatever, and all unconsciously, the fingers are with

great frequency raised to the lips or the nose. Who can doubt that if the salivary glands secreted indigo the fingers would not continually be stained a deep blue, and who can doubt that if the nasal and oral secretions contain the germs of disease these germs will not be almost as constantly found upon the fingers? All successful commerce is reciprocal, and in this universal trade in human saliva the fingers not only bring foreign secretions to the mouth of their owner, but there, exchanging it for his own, distribute the latter to everything that the hand touches. This happens not once, but scores and hundreds of times during the day's round of the individual. The cook spreads his saliva on the muffins and rolls, the waitress infects the glasses and spoons, the moistened fingers of the peddler arrange his fruit, the thumb of the milkman is in his measure, the reader moistens the pages of his book, the conductor his transfer tickets, the 'lady' the fingers of her glove. Everyone is busily engaged in this distribution of saliva, so that the end of each day finds this secretion freely distributed on the doors, window sills, furniture, and playthings in the home, the straps of trolley cars, the rails and counters and desks of shops and public buildings, and, indeed, upon everything that the hands of man touch. What avails it if the pathogens do die quickly? A fresh supply is furnished each day. Besides the moistening of the fingers with saliva and the use of the common drinking cup, the mouth is put to numberless improper uses which may result in the spread of infection. It is used to hold pins, string, pencils, paper and money. The lips are used to moisten the pencil, to point the thread for the needle; to wet postage stamps and envelopes. Children 'swap' apples, cake, and lollipops, while men exchange their pipes and women their hatpins. Sometimes the mother is seen 'cleansing' the face of her child with her saliva-moistened handkerchief, and perhaps the visitor is shortly after invited to kiss the little one.

"Children have no instinct of cleanliness, and their faces, hands, toys, clothing, and everything that they touch must of necessity be continually daubed with the secretions of the nose and mouth. It is well known that children between the ages of two and eight years are more susceptible to scarlet fever, diphtheria, measles, and whooping-cough than at other ages, and it may be that one reason for this is the great opportunity that is afforded by their habits at these ages for the transfer of the secretions. Infants do not, of course, mingle freely with one another, and older children do not come in close contact in their play, and they also begin to have a little idea of cleanliness."

**Domestic Animals**, especially cats, dogs and horses, have been suspected as sources of infection, but the evidence lacks definite foundation of fact. Savage<sup>20</sup> recently reexamined the whole subject, and concluded that cats do not suffer from diphtheria. He failed to infect young kit-

<sup>20</sup> *Jour. Hygiene*, XVIII, 448, Feb., 1920.

tens with cultures of the Klebs-Löffler bacillus, and found that these organisms usually disappear within 24 hours when implanted into the nasal cavity and upon the throat. He concludes that there is no evidence that cats serve as carriers of diphtheria. On the other hand, Major Simmons<sup>21</sup> has isolated virulent diphtheria bacilli from two cats which were pets of a person who contracted a fatal diphtheritic pharyngitis. It is quite probable that domestic animals, especially pets, may occasionally transfer the infection.

**Milk-borne Diphtheria.**—The diphtheria bacillus grows well in milk without appreciably changing its flavor or appearance. Trask collected 23 diphtheria epidemics from the literature between 1895 and 1907. Fifteen of these occurred in the United States and 8 in Great Britain. The milk is usually contaminated by cases of the disease occurring on the farm or at the dairy or milk shop. In some cases the diseased person milks the cows or the same person nurses the sick and handles the milk. In two instances the outbreak was supposed to be due to disease of the cow. One instance studied by Dean and Todd is instructive. In certain families supplied with milk from two cows there occurred two cases of clinically typical diphtheria and three of sore throat, whereas in another family using the milk, only after sterilization, no case occurred. One of the cows had mammitis and furnished a scanty,ropy, semi-purulent, and slightly blood-tinged milk. The Klebs-Löffler bacilli were isolated in all cases and also from the milk of the cow with mammitis. Experiments justified the conclusion that the ulcers upon the udder of the cow with mammitis had become secondarily infected with *B. diphtheriae*, accidentally from some apparently healthy person. Usually, however, the milk is infected directly from a case or carrier.

The diphtheria bacillus is not killed by freezing. An outbreak at Newport, R. I., and vicinity, due to ice cream, was reported by McCoy, Bolton and Bernstein.<sup>22</sup>

**Bacillus Carriers.**—It was in the case of diphtheria that the danger of bacillus carriers was first realized. It is now known that persons who come in contact with diphtheria patients are very apt to harbor diphtheria bacilli, though they may remain in good health. It is also now well known that a certain percentage of the population at large harbor the diphtheria bacilli in their nose or throat, even though they have had no known association with the disease. Graham-Smith found that 66 per cent. of the members of the family to which the diseased person belonged were infected; the proportion being higher (100 to 50 per cent.) in families in which no precautions were taken to isolate the sick, and much lower (10 per cent.) when such precautions were taken. Of the more distant relatives examined, 29 per cent. were found to be carriers.

<sup>21</sup> *Am. Jour. Med. Sc.*, CLX, 589, Oct., 1920.

<sup>22</sup> *Public Health Reports*, Vol. XXXII, No. 43, Oct. 26, 1917.

Bacilli were found in 37 per cent. of persons in attendance on the sick. Observations of the inmates of hospital wards and institutions showed that 14 per cent. are likely to give positive cultures when diphtheria occurs among them. In infected schools 8.7 per cent. of the pupils were found to be bacillus carriers. In New York, Scholley examined 1,000 children from the tenement districts, and found 18 with virulent and 38 with non-virulent bacilli. Moss, Guthrie and Gelien found *B. diphtheriae* in 3.61 per cent. of 1,217 school children in Baltimore, and 3.48 per cent. of 1,290 individuals in the city at large. Only 18 per cent. of the positive cultures were virulent. Goldberger and Williams examined 4,093 healthy persons in Detroit in 1914 and found 0.928 per cent. to harbor morphologically typical bacilli, and 0.097 per cent. to be carriers of virulent bacilli. Diphtheria was unduly prevalent at the time. Slack, Arms, Wade, and Blanchard took cultures at the beginning of the school year from about 4,500 pupils in the Brighton district, Boston. Diphtheria was not prevailing at the time. Nevertheless, at least 1 per cent. of all these healthy school children were found to carry morphologically typical diphtheria bacilli. It is estimated that this is the average ratio in the population at large.

The virulent and the non-virulent strains of the diphtheria bacillus remain true to type. All attempts to exalt the pathogenicity of the avirulent strains by passage through animals have failed. The avirulent diphtheria bacilli do not produce toxin, do not kill guinea-pigs, and do not produce antitoxin; the virulent and avirulent strains look alike under the microscope. The virulent strain can therefore only be distinguished by animal tests.

Diphtheria bacilli from patients with diphtheria and from carriers who have been in contact with such patients are practically always virulent. Diphtheria is kept alive by these virulent strains in immune persons. Carriers with the avirulent strain may be disregarded. None of the children in the Brighton district above mentioned had any known association with the disease, nor did they afterward develop diphtheria. The danger of such carriers is nil. *The dangerous carrier is he who harbors the virulent strain, and this is usually obtained from the patient, convalescent, or from a third person who has come in contact with the patient.*

The virulent bacilli may be differentiated from the avirulent strains by injecting pure cultures into guinea-pigs. Zingher and Soletsky<sup>23</sup> have improved Neisser's method by using 2 guinea-pigs for the testing of from 4 to 6 different strains. One guinea-pig serves as a control and receives about 200 units of antitoxin intracardially at the time of making the test, or intraperitoneally 24 hours before. Both pigs are injected with suspensions of the cultures to be tested intracutaneously. A fresh 24-hour

<sup>23</sup> Zingher and Soletsky: Proceedings of the New York Pathological Society, N. S., Vol. XV, Nos. 1 and 2, January and February, 1915.

growth from an ordinary Löffler slant is suspended in 25 to 30 c. c. of normal salt solution; 0.1 c. c. is injected into the skin. The results of the tests are noted in 24 to 48 hours. Virulent strains produce a definite local inflammatory lesion, which shows a superficial necrosis in 18 to 72 hours. In the control pig the skin remains normal. With non-virulent strains no lesions will be found in either control or test animal. It is plain that the control of diphtheria outbreaks in institutions, camps, on shipboard, schools, and in similar places, where a number of people are crowded together, as well as the final control of the disease in cities and towns, depends eventually upon the recognition of true carriers and their isolation.

Diphtheria bacilli disappear in about 50 per cent. of cases by the time the local membrane has disappeared. The bacilli persist in about 5 per cent. of persons at the end of two months, about 2 per cent. at the end of 3 months, and approximately 1 per cent. continue as chronic bacillus carriers. The virulence is not lessened during the carrier condition.

It is important to remember that diphtheria bacilli may be either in the nose or throat or both. It is therefore essential to take nose as well as throat cultures in searching for carriers. Two, three or more examinations may be necessary to discover all the carriers.

Many methods have been used to cure diphtheria carriers. These consist of liquid antiseptics applied as swabs, sprays or gargles; the inhalation of antiseptic vapors; the use of diphtheria vaccine, toxin, antitoxin, and antibacillary serum; also toxins of the *Bacillus pyocyaneus*; and the introduction of cultures of staphylococci, yeast and other micro-organisms. Hektoen and Rappaport<sup>24</sup> suggested the use of kaolin. Good results have sometimes followed but mostly failed in all the methods so far tried.

The diphtheria bacilli probably do not long persist upon normal mucous membranes, but continue in pockets, folds, crypts of the tonsils, fissures of adenoids, spaces about the turbinates, the sinuses connected with the nasal cavity, and in any irritated, inflamed or ulcerated portion of the mucous membrane. Therefore, the removal of enlarged tonsils, polypi, foreign bodies, and other sources of irritation and inflammation has resulted in the cure of diphtheria carriers. The first indication is to treat the mucous membrane of the upper respiratory passages so as to get it in a normal condition.

The disappearance of the bacilli from the throat and nose cannot be hastened by the usual injections of antitoxin. Diphtheria antitoxin neutralizes the toxin, but does not harm the bacilli. A serum containing agglutinins has been used. This serum in powdered form is blown into the throat. The diphtheria bacilli are supposedly agglutinated and may then be more readily washed away by gargling and douching. A sub-

<sup>24</sup> *Jour. A. M. A.*, LXIV, 24, June 12, 1915 p. 1991.

stance proposed by Emmerich known as "pyocyanase" has been used. This contains a ferment from bouillon cultures of the *Bacillus pyocyaneus*. It is applied locally and acts by its power of bacteriolysis.

Encouraging results have been reported by "over-riding" the throats of diphtheria carriers with suspensions of *Staphylococcus pyogenes aureus*, which are sprayed into the throat and nose. The method was introduced by Schiotz, in 1909, who reported the prompt disappearance of diphtheria bacilli in six carriers. Page, also Catlin, Scott and Day, Lorenz and Ravenel, and others, have reported successful results.

Hewlett and Nankivell, and also Petruschky, report encouraging results in clearing up diphtheria carriers by the subcutaneous injection of a diphtheria vaccine.

We must acknowledge that all these measures often fail. The relief of bacillus carriers is one of the unsolved problems in preventive medicine.

**Diagnosis.**—The diagnosis of diphtheria often rests upon a combination of clinical symptoms and laboratory findings. Positive cultures alone do not necessarily mean clinical diphtheria, even though sore throat and fever are present. Cases of streptococcal tonsillitis, with follicular patches resembling false membrane, occur in diphtheria bacillus carriers. Such persons give negative Schick reactions, and do not have clinical diphtheria, despite the positive findings in cultures taken from their throats. It is important to remember that the diagnosis of clinical diphtheria cannot be made in the laboratory as a result of finding virulent diphtheria bacilli in cultures. Diphtheria often begins insidiously, and valuable time is lost in waiting for false membrane or other symptoms; cultures should be taken of all sore throats in order to exclude or confirm diphtheria.

On the other hand, negative cultures are significant in excluding diphtheria, provided the material is taken from the proper place and good technic is used.

Always give antitoxin in a clinical case of diphtheria at once, without waiting for laboratory confirmation of the diagnosis. No harm will be done and lives will be saved by this rule, for time is the important element in the life-saving properties of antitoxin. In mild cases, subcutaneous or intramuscular injection may be used, but in severe cases intravenous injection is called for.

**Resistance.**—The diphtheria bacillus has less resistance to adverse conditions than the majority of the spore-free bacteria. It is more readily destroyed by light, heat, and disinfecting substances than the typhoid bacillus. In this regard it corresponds more to the frailer streptococci. Under certain circumstances the diphtheria bacillus resists drying for a long time. When enclosed in the false membrane or other albuminous substances, they may remain virulent for some months. It is not killed by freezing.

## IMMUNITY

Immunity to diphtheria is mainly an antitoxic immunity and persists a variable time. Second attacks sometimes occur within a few weeks while the patient is still in the hospital. Reiche<sup>25</sup> states that 5.8 per cent. of 4,761 cases of diphtheria in Hamburg were known to have had a previous attack. He presents further data to confirm the absence of any lasting immunization by a single attack of diphtheria. A positive Schick reaction may be obtained in children who have recovered from the disease. Graef and Ginsberg<sup>26</sup> have shown by the Schick reaction that immunity obtained by an attack of the disease lasts from a month to several years, varying greatly in different individuals, and being very brief in children. The fact that healthy persons may harbor virulent bacilli upon their mucous membrane for a long time without contracting the disease shows the high grade immunity enjoyed by many individuals, due to antitoxin constantly in the blood. Persons vary markedly in susceptibility. During the first few months of life there is a very high grade immunity. Antitoxin is transmitted to the fetus through the placental circulation and to the infant in the mother's milk. This immunity during the early months of life is passive and soon wears off, so that by the end of two years 70 per cent. are susceptible. After this period, children begin to manufacture their own diphtheria antitoxin, so that the percentage of susceptible children gradually decreases until the twentieth year, when only 12 per cent. give a positive Schick reaction; in other words, 88 per cent. of the adult population are immune to diphtheria.

As a result of extensive studies by means of the Schick test conducted under the direction of Dr. W. H. Park, it has been found that susceptibility to diphtheria is present in about the following proportions:

Age	Per Cent. Susceptible Positive Schick Re- action	Per Cent. Immune Negative Schick Re- action
Under 3 months.....	15	85
3 to 6 months.....	30	70
6 months to 1 year.....	60	40
1 to 2 years.....	70	30
2 to 3 years.....	60	40
3 to 5 years.....	40	60
5 to 10 years.....	30	70
10 to 20 years.....	20	80
Over 20 years.....	12	88

<sup>25</sup> Reiche, F.: Reinfection with Diphtheria. *Med. Klin.*, Berlin, Oct. 12, IX, No. 41, pp. 1663-1708.

<sup>26</sup> *Jour. A. M. A.*, LXIV, 1915, p. 1205.

The curve of these figures corresponds closely to the age incidence of the disease.

**Passive Immunity.**—This can be induced by injecting antitoxin. The usual immunizing dose is 1,000 to 1,500 units for adults and 750 to 1,000 units for children. The protection thus afforded disappears in 3 to 8 weeks. A second injection of antitoxin renews the immunity, which, however, lasts a still shorter time. Passive immunity, while occasionally of great practical service in individual prophylaxis, cannot be depended upon to control epidemics.

The great advantage of passive immunity is that it is prompt; the disadvantages are that it lasts a brief time, produces serum reactions, and is relatively much more expensive than active immunity.

**Active Immunity.**—This can be induced by injecting a mixture of toxin and antitoxin.<sup>27</sup> The toxin and antitoxin are mixed so that the toxin is not quite neutralized; in other words, there is some free poison in the mixture. This is accomplished by adding about 86 per cent. of an L<sub>+</sub> dose of toxin to each unit of antitoxin. Such a mixture contains free *toxon*, but no uncombined *toxin*. Five c. c. of this mixture injected into guinea-pigs does not produce acute symptoms of toxic irritation and poisoning, the result of *toxin*, but causes late paralysis, which begins about the 10th day, the result of *toxon*. The mixture is diluted so that three units of antitoxin and about 3 L<sub>+</sub> doses of *toxin* are contained in each c. c.

The dose of toxin-antitoxin mixture is 1 c. c. subcutaneously, repeated every week, until three injections are given. Children react less than adults and therefore can be given a full dose.<sup>28</sup> The immunity appears slowly, sometimes in eight to twelve weeks, but once established seems lasting. Park finds that children immunized five years ago still have antitoxin in their blood as demonstrated by negative Schick reactions. One injection will immunize about 60 per cent., two injections about 80 per cent., and three injections from 90 to 99 per cent. A small percentage of persons will show a positive Schick reaction at the end of three months, after three injections of the toxin-antitoxin mixture. Such persons may be given two or three more injections and in this way an active immunity may be developed in almost all susceptible persons.

An immunizing dose of antitoxin interferes with the production of an active immunity with toxin-antitoxin mixtures. In other words, an overneutralized toxin interferes with the stimulation of antibody formation.

By actively immunizing all children under 18 months and only those children over 18 months who give a positive Schick reaction, we can

<sup>27</sup> This method was suggested by Theobald Smith, but first attempted by Behring in 1912. It has been studied especially by Park and Zingher of the New York City Department of Health.

<sup>28</sup> Infants do not react at all and may be given 1.5 c. c.

render the child population immune to diphtheria, and tide it over the period of greatest susceptibility. It should be remembered that in adult life the great majority (88 to 90 and *even 95 per cent.*) are naturally immune. The percentage is higher in urban than rural districts.

The advantages of active immunity, produced by injecting toxin-antitoxin mixture are that it is lasting, cheap and simple, and the reactions are slight. Its only disadvantage is that it takes several weeks or months to appear.

**The Schick Reaction.**—The presence or absence of immunity in any individual may readily be determined by the Schick test, which tells whether antitoxin is present or absent in the blood of that individual. The Schick reaction is made by injecting a small amount of diphtheria toxin *into the skin*. The precise quantity used is 1/50th of a minimum lethal dose of diphtheria toxin for a 250-gram guinea-pig. This amount of toxin is diluted so that it is contained in 0.1 or better 0.2 c. c. of salt solution. The injection must be made *into* and not under the skin. A positive reaction at the site of the injection means absence of antitoxin, that is, a susceptible individual. A negative reaction means the presence of antitoxin, hence immunity.

A *positive* reaction is indicated by redness at the site of injection which appears gradually and becomes distinct in 24 to 48 hours, reaching its height on the third or fourth day. The reaction then consists of a circumscribed area of redness and slight infiltration, about one to two centimeters in diameter. The degree of redness and infiltration varies with the relative susceptibility of the individual. The reaction slowly disappears leaving a definite circumscribed scaling area of brownish pigmentation, which persists three to six weeks. A positive reaction represents the effect of an irritating toxin upon tissue cells that are not protected by antitoxin. The reaction is sufficiently delicate to indicate less than 1/30th of a unit of antitoxin in each cubic centimeter of blood serum. Such persons are susceptible to diphtheria.

The intensity of the reaction varies. A well-marked redness indicates an almost complete absence of antitoxin. Faint reactions point to the presence of very small amounts of antitoxin. All gradations are observed.

In a *negative* reaction, the skin at the site of injection remains normal. The toxin is neutralized by the antitoxin, and therefore causes no irritation. Such persons are immune and need not fear diphtheria. A negative reaction in a child that has reached the age of three years indicates an immunity that is probably permanent. No instance has yet been reported of an individual with a negative reaction contracting diphtheria, even though exposed to the disease, or after becoming carriers of virulent diphtheria bacilli.

A *pseudoreaction* represents a local anaphylactic response to pro-

teins in the material injected. This reaction is urticarial, appears within 6 to 18 hours, reaches its height in 36 to 48 hours, and disappears on the third or fourth day, when the true reaction is at its height. Control tests should therefore always be made.

Pseudoreactions occur only in older children and adults, not in infants. *Combined reactions* also occur, that is pseudo and true at the same time. The rule is to retest all doubtful cases or to play on the side of safety by considering them positive reactions.

*Control tests* consist in injecting toxin heated to 75° C. for five minutes. The reaction at the site of the control will help interpret the reaction at the site of the test injection. The accuracy of the Schick test depends upon the strength of the toxin, the technic of the test, and the interpretation of the reaction.

We therefore possess a ready method of determining who is susceptible and who is naturally immune. Persons who react negatively to the Schick test will not develop diphtheria. Therefore when an epidemic breaks out, such persons need not be treated with prophylactic doses of diphtheria antitoxin.

The Schick test shows a striking similarity in reactions in families. If the youngest child of a family has a negative reaction all the older children are likely to be negative, and if the older children are positive the young ones are also. When variations are found, the younger children show the positive reaction (Park). The Schick reaction may be used to differentiate between clinically doubtful cases of diphtheria, in experimental work, and in the handling of diphtheria epidemics in institutions, etc., and it is particularly applicable as a preliminary measure for all persons who have been exposed to diphtheria.

### THE CONTROL OF OUTBREAKS

Diphtheria frequently appears in asylums, hospitals, camps, jails, on shipboard, and similar places. Under these conditions of crowding, the disease has a highly contagious tendency. It may, however, be controlled with every assurance of success by the application of well-tried measures.

The most important measure to suppress diphtheria is to isolate all cases and all carriers. This is easier to do in an institution, or limited compound than in the population at large. The isolation of both cases and carriers is the first of our preventive measures. The most radical is the active immunization of all susceptible individuals with toxin-antitoxin mixture.

The following measures are recommended for the control of an outbreak:—(1) The recognition and quarantining of cases; (2) the finding and isolation of carriers; (3) the discovery of the susceptible by

means of the Schick test; (4) active immunization of all susceptible persons; (5) inspection of all susceptible persons every 12 or 24 hours, and the use of antitoxin upon the first appearance of symptoms; (6) disinfection, laboratory facilities, skilled epidemiologists, and other administrative measures.

**Recognition and Quarantining of Cases.**—These are the immediate demands. It should be remembered that diphtheria often comes on insidiously and that the patient may have his throat plastered with false membrane of three or four days' standing before feeling ill enough to attract attention. Early recognition of the disease is important both for successful treatment and prevention. In all endemic centers the examination of the throat, especially of children, should be made a routine procedure by practicing physicians. In outbreaks a daily inspection and taking of temperatures morning and evening will detect cases early.

In hospitals, cases may be isolated in cubicles, or separated by sheets. Gauze masks may also be used. Careful nursing technic is essential to prevent cross infections.

Convalescents should not be released from quarantine until at least two cultures taken from both the nose and throat are negative.

**Finding and Isolating Carriers.**—Throat and nose cultures from all exposed persons and from all persons in an institutional epidemic should be made. All positive carriers based upon morphologic diagnosis should be isolated. At a later date, when time permits, the carriers of avirulent bacilli may be released. It is sometimes necessary to go through a camp or school twice, thrice, or oftener to detect all the carriers, or to discover new ones.

While it is practical to isolate all the carriers in a limited outbreak, such as a camp, ship, or asylum, this is not always feasible in the community at large. Yet most of the dangerous carriers even in a metropolitan city can be discovered by taking cultures from all persons closely associated with cases.

The bacilli frequently grow in the mucous membrane of the nose and nasal pharynx without anything to indicate their localization. Unless cultures are taken from the nose, many carriers will be overlooked, leaving a large loophole in our preventive measures. Ward and Henderson, in a public school epidemic in Berkeley in 1907, found that all attempts to isolate infected children had no effect on the epidemic so long as they made throat cultures alone. When they took both nose and throat cultures and quarantined all the children showing positive cultures, the epidemic stopped.

Good results can be obtained only where care is exercised in obtaining the material and skill used in the technic of the bacteriological examination.

Diphtheria bacilli sometimes leave the body in the discharges from middle ear disease, and occasionally also from infected wounds.

**Schick Reaction.**—As soon as practical, all those exposed to the infection, whether in a family or in an epidemic focus, should be tested for immunity by the Schick test. In an institution, both the inmates and the administrative force should be tested. No special concern need be given those who react negatively, for they are immune and will not contract the disease. Such persons, however, may be carriers of virulent strains, in which case they should be isolated.

**Active Immunization.**—All those who show a positive Schick reaction should at once be given the toxin-antitoxin mixtures. Three successive injections of 1 c. c. at intervals of a week are given. The immunity comes on slowly (2 to 12 weeks). Such individuals should therefore be carefully inspected every day, so that the first indications of infection may be met with an injection of antitoxin. Under this system, cases of the disease may arise during the time it takes these persons to develop an active immunity, but with the timely use of antitoxin no deaths will occur.

This is the most effective method of eradicating diphtheria, both in endemic centers as well as in epidemic foci. The results obtained are permanent. It requires time, and very careful supervision of all the details, with a corps of skilled and trained technicians, to carry it out successfully.

An immunizing dose of antitoxin should not be used to tide over the interval it takes for toxin-antitoxin immunity to become established, because this interferes with the production of active immunity. In other words, the methods of active and passive immunization should not be used at the same time.

For the population at large, the best time to test susceptibility with the Schick reaction is between 6 months and 2 years. At this time of life, the percentage of positive Schick reactions is largest, and the susceptibility to diphtheria as well as the mortality from the disease is greatest. All those showing positive reactions at this period should be immunized with the mixture (see page 200). Very young infants do not react at all to the toxin-antitoxin injections, and Park proposes to immunize all at this period of life, without a Schick test.

Zingher<sup>29</sup> recommends the following procedures for the protection of children:—(1) All children over 18 months of age in the entire community should have their susceptibility to diphtheria determined by means of the Schick test, and the reaction which they show should be noted either in institutional records or in the records of the family physician. (2) In infants below 18 months of age, the Schick test is not necessary because a negative reaction may give rise to a false sense

<sup>29</sup> Reprint No. 72, Dept. of Health, New York City, Nev., 1918.

of security. Very young infants may exhibit a negative Schick test owing to the immunity passively acquired from the mother, but inasmuch as this type of immunity is transient, it is safer to assume that no child under 18 months possesses permanent immunity. (3) All infants below 18 months of age accordingly should be actively immunized with three doses of 1 c. c. each of diphtheria toxin-antitoxin mixture, irrespective of the reaction to the Schick test which the infant might show at the time of immunization. (4) All children over 18 months of age who give a positive Schick test should be immunized by receiving three subcutaneous injections of 1 c. c. each of toxin-antitoxin at intervals of 7 days. (5) All children immunized by this method should be retested three months after the last injection and reimmunized if they should by any chance still give a positive Schick reaction.

**Passive Immunization.**—This consists in injecting diphtheria antitoxin. The customary immunizing dose is 1000 units. Schick recommends 50 units per kilogram of body weight. The protection wears off in 3 to 8 weeks, but the immunizing dose can be repeated every 2 or 3 weeks until the danger is passed.

Antitoxic immunity cannot be depended upon to stamp out the infection. It has several disadvantages that should not be disregarded. The bacilli remain in the throats of those immunized and the disease continues to crop out from time to time as the antitoxin disappears. Where large numbers are involved the method is very expensive, time-consuming, and the resulting serum reactions often disturbing, especially where repeated immunization is called for. A blind reliance upon antitoxic immunity has proved disappointing and futile in many institutional outbreaks. In the end, the active immunity induced by toxin-antitoxin mixtures does not take much more time and is much more certain.

Antitoxic immunity has a distinct place in personal prophylaxis and in selected individual cases, especially in family practice, but will gradually be replaced with active immunization.

**Disinfection.**—Disinfection has a place in controlling the spread of the infection. The discharges from the patient should be burned. All fabrics, bed and body linen, that have come in contact with the discharges from the mouth and nose, and all objects such as spoons, cups, thermometers, toys, etc., that have been mouthed should be boiled, steamed or soaked in one of the standard germicidal solutions. The hands of the nurse need attention and proper nursing technic should be carried out.

Terminal fumigation is of little avail. A special cleansing and disinfection of floors, walls, door knobs, bed frames, and other surfaces that have been contaminated will suffice. The germicidal solutions available are bichlorid of mercury, 1 to 1000; carbolic acid, 2.5 per cent.; formalin, 10 per cent.; or liquor cresolis compositus, 1 per cent. They should be used hot.

**Administrative Measures.**—Diphtheria requires a well trained force familiar with the modern problem and skilled in the technical sides of diagnosis and the Schick reaction. Laboratory facilities are indispensable. With an adequate force, including an experienced epidemiologist, diphtheria should never get out of hand in any community, and epidemics should be promptly controlled. Education of the public and profession is part of the program. Personal hygiene and sanitary habits must be taught and encouraged. Care should be taken that the infection is not spread by tableware, handkerchiefs, wash bowls, and articles in common use. Better sanitary control over restaurants and soda water fountains should be maintained. All table ware should be scalded before it is again used. Sanitary habits regarding "hand to mouth infection" and measures to "screen the sneeze" need emphasis in nursery, schools and workshops.

In almost all communities diphtheria is now one of the diseases which must be reported to the health authorities. The houses are placarded and the cases isolated. There is no great objection to treating a case of diphtheria in the household provided the patient and the nurse may also be quarantined from the rest of the household. Under these circumstances and with intelligent care and disinfection at the bedside there is little danger to the rest of the family; but the great menace that some of the members of the family will become bacillus carriers of a dangerous type makes it advisable to treat all cases of diphtheria in a special hospital.

All outbreaks should of course be investigated as to their source. The possibility of milk-borne infection is usually evident. In any case, milk should be pasteurized and care taken to prevent infection in the kitchen or in serving and handling food.

Schools need not be closed during an epidemic of diphtheria; in fact, better results will be achieved by daily inspection, and examination of cultures from the nose and throat of each pupil from time to time. The well children of a household, where a person is ill with diphtheria, should be excluded from school until one week has expired from the date of the last exposure, unless showing two negative cultures from throat and nose. All other members of the household may be allowed to continue their usual occupations, except those who are engaged in the handling of milk.

**Responsibility of the Medical Profession.**—People still die of diphtheria—usually because the diagnosis is not made early and because diphtheria antitoxin is not given in time.

Diphtheria antitoxin is a specific and sovereign remedy. When given in sufficient amounts during the first 24 hours of the disease it reduces the mortality to practically nil. Upon the first appearance of sore throat, fever, or other suggestive symptoms in persons who are exposed

to diphtheria, a full dose of 3,000 to 10,000 units should be administered subcutaneously without delay. It is absorbed more quickly when given intramuscularly. In very toxic cases, or for late use, it acts most quickly when given intravenously. In order to obtain the full life-saving benefits of diphtheria antitoxin, it should be given early in the disease. Time is the most important factor. When the damage to the cells has been done, it may be too late. It is not always advisable to wait for bacterial confirmation.

Many unnecessary deaths from diphtheria occur. In New York City alone, over 1,000 deaths occur annually, approximately 20 per 100,000 of population. Similar rates prevail in Rhode Island, Pennsylvania, Kentucky, North Carolina, Massachusetts, Michigan, and elsewhere.

In a study of 1,000 deaths recently made by Carey<sup>30</sup> of the Massachusetts State Department of Health, it is shown that the useful knowledge and facilities for dealing with diphtheria are still utilized far too little. In 23.1 per cent. of the cases, the patient was ill a week before the physician was called. In 4.2 per cent., the patients had been ill from one to two weeks before they received attention. In 7.6 per cent. of the deaths, the disease was not recognized during life. In a number of fatal cases, the physician delayed antitoxin treatment by waiting for laboratory confirmation of the diagnosis. In not a single instance was the antitoxin given intravenously. A similar situation was found in New York City—"with a diagnostic laboratory service unsurpassed, with Schick test outfits, antitoxic serum, and active immunization outfits practically at their elbow, the physicians of New York were charged with insufficient or delayed utilization of these aids and with responsibility of continued prevalence of fatal cases of diphtheria." Every death from diphtheria should be investigated and the responsible party brought to task. The facts indicate the further need of education of both the profession and the public, in order to save lives from this and other preventable infections.

The disease often begins insidiously and the true diagnosis is often not made until too late for antitoxin to exert its life-saving power.

### PREVENTION OF POSTDIPHTHERITIC PARALYSIS

It has been observed that postdiphtheritic paralysis is more frequent since the use of antitoxin than before the days of serum therapy. This is due to the fact that many cases now recover that would formerly have died. It is also due to the fact that diphtheria antitoxin is sometimes used too late, thus neutralizing only the acute effects of the *toxin*, but not neutralizing the after effects of the *toxon* which acts specifically upon the nerves. The prevention of postdiphtheritic

<sup>30</sup> *Boston Med. and Surg. Jour.*, CLXXX, 3, p. 67, Jan. 16, 1919.

paralysis, therefore, consists in giving sufficient amounts of antitoxin *early* in the disease. The antitoxin does not influence the paralysis after it has once appeared.

### PREVENTION OF SERUM SICKNESS AND ANAPHYLACTIC SHOCK

This subject may appropriately be considered here, although it is a condition that may follow the injection of any alien serum into the system. Serum sickness is a syndrome which frequently follows the injection of horse serum into man. The symptoms come on after about 8 or 10 days following the injection. They consist of various skin eruptions, usually urticarial or erythematous in character; also fever, vomiting, edema, glandular and splenic enlargements, rheumatic-like pains in the joints and muscles; and albuminuria. The eruptions may be either local or general, and sometimes resemble those of scarlet fever or measles. Serum sickness has nothing to do with the antitoxin, but is caused entirely by the foreign proteins contained in the horse serum. It may be produced with normal horse serum as well as with antitoxic horse serum. The studies upon anaphylaxis have thrown much light upon the nature of this complication. The occurrence and severity of the symptoms depend upon the amount of foreign protein injected and the sensitiveness of the individual. Fortunately, this form of anaphylactic reaction soon passes away and is never serious. Under certain circumstances, however, there may be an accelerated or immediate reaction threatening in its consequence or even leading to death. Rosenau and Anderson have collected some 19 cases of sudden death following the injection of horse serum, and they know of more instances which have not appeared in the literature. This unusual and serious complication comes on within 5 or 10 minutes of the injection, and is characterized by collapse, unconsciousness, cyanosis, labored respiration, and edema. The heart continues to beat after respiration has ceased. The entire picture is an exact counterpart of the anaphylactic shock so readily reproduced by a second injection of horse serum or other foreign protein in the guinea-pig. Contrary to the experimental work on the lower animals, the cases of sudden death in man follow the first injection of horse serum. The serious symptoms and death in these cases are not due to any inherent poisonous property in the antitoxic serum, but result entirely from a hypersusceptibility of the individual. Just how man becomes sensitized in these cases is not known (page 599). Most of the cases occur in healthy persons who give a history of asthma or discomfort when about horses. This is a practical and important point, and should be inquired into before horse serum of any kind is injected. Horse serum should not be injected into such individuals

unless the indications are clear, and then only with a statement as to the possible outcome. Bovine serum may be used.

Diphtheria antitoxin may be given without fear of anaphylactic shock in cases of diphtheria. The few serious accidents have occurred only with prophylactic doses in healthy persons. There is no instance on record of diphtheria antitoxin causing fatal anaphylactic shock in a person ill with diphtheria. We now have an experimental confirmation of this, for Bronfenbrenner,<sup>31</sup> working in my laboratory, has shown that diphtheria toxin prevents anaphylactic shock in sensitized guinea pigs. *It is therefore incalculable to delay or hesitate to use full therapeutic doses of antitoxin in diphtheria.*

**Desensitization.**—In order to prevent anaphylactic shock following the use of serum in pneumonia and other diseases in which large amounts of alien proteins are injected, desensitization may be attempted. Sensitiveness should first be tested by injecting minute amounts of the alien protein into the skin. Within an hour a characteristic local edema and erythema takes place at the site of the injection. Desensitization may be accomplished by injecting exceedingly minute amounts subcutaneously and repeating this every half-hour or hour with doses of gradually increasing size. Persons may also be desensitized by injecting 0.5 to 1.0 c. c. of the serum to be used, subcutaneously, several hours before giving intravenous injections. Whether the patient is susceptible or not, intravenous injections should be given very slowly.

Friedberger and Mita<sup>32</sup> found it possible to avoid all symptoms of anaphylaxis in experimental work with guinea-pigs by injecting the serum extremely slowly. When thus introduced animals are able to tolerate an amount far beyond the ordinary lethal dose.

Adrenalin, pituitrin, chloral, chloroform, and atropin in full therapeutic amounts are claimed to ameliorate or even prevent anaphylactic shock, but it must be admitted that none of the above procedures is wholly satisfactory.

**Historical Note and References.**—A complete summary and bibliography of diphtheria up to 1908 will be found in the system edited by Nuttall and Graham-Smith entitled "The Bacteriology of Diphtheria," containing articles by Löffler, Newsholme, Mallory, Graham-Smith, Dean, Park, and Bolduan; Cambridge University Press, 1908.

The modern clinical description of the disease is, by common assent, attributed to Bretonneau, of Tours, in 1826: *Traité de la diphthérie*. Des inflammations spéciales du tissu muqueux et au particulier de la

<sup>31</sup> Proceed. Soc. Exp. Biol. and Med., Feb. 16, 1920.

diphthérie ou inflammation pelliculaire, connue sous le nom de croup, d'angine maligne, d'angine gangréneuse, etc., Paris.

The bacillus of diphtheria was first cultivated and adequately described by Löffler, 1884: Untersuchungen über die Bedeutung der Mikroorganismen für die Entstehung der Diphtherie beim Menschen, bei der Taube und beim Kalbe. *Mitth. a. d. k. Gesundheitsamte*, ii, 451.

The classical article in which Behring and Kitasato announced their discovery of diphtheria antitoxin in 1890 will be found in *Deutsche med. Wochenschr.*, xvi, 1113. Ueber das Zustandekommen der Diphtherieimmunität und die Tetanusimmunität bei Tieren.

Ehrlich's important work, in which he laid the foundations of his side-chain theory and established the present satisfactory method of standardizing diphtheria antitoxin, will be found in the following: Die Werthbemessung des Diphtherieheilserums und deren theoretische Grundlagen. *Klin. Jahrb.*, Jena, v, 6 (2), 1897, pp. 299-326. Ueber die Constitution des Diphtheriegiftes. *Deut. med. Woch.*, Leipzig, v, 24 (38), 1898, pp. 597-600. Croonian lecture. On Immunity with Special Reference to Cell Life. *Proc. Roy. Soc.*, London, v, 66, pp. 424-448, pls. 6-7.

The official method for standardizing diphtheria antitoxin in this country and the principle upon which it is based are described by Rosenau (1905), The Immunity Unit for Standardizing Diphtheria Antitoxin (based on Ehrlich's normal serum). *Hygienic Laboratory Bull.*, No. 21, P. H. and M. H. S., Washington, Govt. Print. Office, 92 pp.

The Schick test was first described in the *Münch. med. Wochenschr.*, Nov. 25, 1913, p. 2608.

### VINCENT'S ANGINA

Vincent's angina was first described by Professor Vincent in 1898. It is an important disease in itself, and also because it is very likely to be mistaken for diphtheria. Vincent's angina is due to a fusiform bacillus and an accompanying spirillum (spirochete?). In early cases the bacilli are usually more numerous than the spirilla, but in more advanced cases the spirilla usually predominate. The organisms are best stained with carbol-gentian violet. Both the spirilla and the bacilli are usually gram negative. They have been grown by Tunncliffe<sup>33</sup> anaërobically in ascitic broth containing a piece of tissue. She regards them as identical for the reason that the spirillum appeared to develop from a pure culture of the fusiform bacillus.

The disease is characterized by slight constitutional disturbance

<sup>33</sup> *Jour. Inf. Dis.*, III, 1, Mar., 1906, p. 148.

and no fever; the temperature rarely goes over 100° F.; there is pain on swallowing; the submaxillary lymphatic glands are enlarged and tender, the lesions are often unilateral; the yellowish-gray membranous exudate is usually easily removed, leaving a raw, bleeding surface; albumin rarely appears in the urine.

The fusiform bacillus and the long spirillum were first demonstrated in cases of ulceromembranous angina, and later found in cases of ulceromembranous stomatitis; also in gingivitis, noma, hospital gangrene, pyorrhea alveolaris, appendicitis, abscesses, and other morbid processes. Noguchi found these organisms in a case of ulcer of the labia, and Vincent himself reported a case of gastro-enteritis in which large numbers of typical organisms were found. Corbus and Harris have described ulcerative balanitis due to this organism, and they called it "the fourth venereal disease."

This infection is peculiar to man; at least, experiments on animals are negative. Second attacks and recurrent attacks occur, indicating that there is little or no immunity conferred. Local applications of arspenamine appear useful, both in treatment and for prophylaxis.

Vincent's angina is often mistaken for diphtheria. It must be differentiated from syphilis. The disease is much more common than is ordinarily supposed. Under military conditions the incidence is greatly increased, and it was a common cause of disability in the World War. The disease is favored by any debilitating condition, such as fatigue, chill, exposure, insufficient and improper food, and excessive use of alcohol and tobacco.

The organisms are found in normal mouths, especially in those with poor teeth and lack of oral hygiene. Campbell and Dyas found a few Vincent's organisms in about 50 per cent. of all swabs taken from the throats of troops at Bramshott. Reckford and Baker<sup>34</sup> found only one carrier in fifty normal individuals, whereas fusiform bacilli and spirilla were found in 90 per cent. of the smears from diseased teeth in a dental clinic.

The disease is spread through the discharges from the lesions and by carriers in the same ways that diphtheria is spread. The prophylaxis is similar; special attention must be given to predisposing factors, such as undernutrition, to oral hygiene, and to measures that improve health.

<sup>34</sup>*J. A. M. A.*, Vol. LXXV, No. 24, p. 1620.

**MEASLES***(Morbilli, Rubeola)*

Measles is usually taken as the type of a contagious disease because it is one of the most readily communicable of all diseases, in this regard ranking with smallpox and pandemic influenza. As a cause of death it ranks high among the acute fevers of children.

In the registration area of the United States, during the twelve years from 1900-1911, 50,000 deaths from measles were recorded, and it is estimated that over 100,000 deaths were caused by measles in the continental United States during the same period. The number of deaths from measles as compared with those of certain other diseases in the registration area during the years 1910 and 1917 is shown in the following table:

Disease	1910		1917	
	Deaths	Deaths per 100,000 Population	Deaths	Deaths per 100,000 Population
Diphtheria and croup.....	11,512	21.4	12,453	16.5
Measles.....	6,598	12.3	10,745	14.3
Scarlet fever.....	6,255	11.6	3,141	4.2
Whooping cough.....	6,148	11.4	7,837	10.4
Cerebrospinal meningitis...	2,272	4.2	6,890	9.1
Infantile paralysis.....	1,459	2.7	.....	....

It is estimated that 10,000 deaths from measles take place each year in the United States. These figures are conservative, for many deaths from measles are recorded as pneumonia.

Measles is an infection peculiar to man. Experimental measles has been produced in monkeys, but the susceptibility is not marked and subject to variations. The virus is contained in the blood, as has been shown by Hektoen, who thus transmitted the disease from man to man. More important from the standpoint of prevention, the virus has been demonstrated in the secretions from the nose and mouth by Anderson and Goldberger. The period of incubation is quite constant (from 9 to 11 days), and the rash appears quite uniformly on the 13th or 14th day after the infection. In Hektoen's two experimental cases the eruption appeared on the 14th day. The cause of measles is not known.

Measles is more or less constantly present in all large cities in the temperate zone; it is less common in the tropics, although it spreads as readily in hot as in cold climates. All races are susceptible; the death

rate is higher in urban than in rural districts.<sup>35</sup> Measles frequently becomes epidemic, usually in the cooler months, in this respect resembling influenza, scarlet fever and smallpox. The epidemics recur cyclically, at intervals of two or three years, with considerable regularity in thickly settled communities. In more sparsely populated areas, these waves recur at longer and more irregular intervals. Levy and Foster noticed that in Richmond, Va., epidemic outbreaks recurred at intervals of about 3 years. They were able to predict and warn against an epidemic prevalence of the disease in the winter of 1910. During 1909, 40 cases of measles occurred in Richmond, but during this year the disease showed no special tendency to spread. In the middle of February, 1910, 8 cases occurred among the pupils of one school and the infection showed a high degree of communicability. According to the history of the disease, an epidemic year was due and an epidemic was predicted. Over 2,000 cases occurred with 26 deaths.

Measles is highly contagious during the præruptive stage, when the nature of the disease is not recognized and when most of the damage is done; it remains contagious for a variable time during convalescence. Recent experimental evidence and clinical experience plainly indicate that the infection of measles soon dies out, and that there is little danger of transmitting the disease after the temperature returns to normal. An isolation of two weeks from the onset of the disease is sufficient in public health work; health officers, however, adopt arbitrary times. For public health purposes the maximum period of incubation is placed at 14 days.

Measles is malignant in virgin soil. An increased virulence is also observed wherever many cases of measles are brought together. This is explained on the theory of cross-infection with the chief complications—streptococci and pneumonia.

**Immunity.**—One attack of measles confers a definite protection against subsequent attacks; second attacks, however, are more commonly reported than in the other eruptive fevers. Some persons are said to have the disease three or four times.<sup>36</sup> The close similarity between rubella (German measles) and rubeola (measles) accounts for many so-called second attacks of measles. As with smallpox, there appears to be no natural immunity to measles—man is exquisitely susceptible to these two infections. There appears to be a relative immunity sometimes of a high grade during the first few months of life, although measles occasionally occurs in infants of a month or six weeks.

<sup>35</sup> Crum, F. S.: A Statistical Study of Measles. *Am. Jour. of Pub. Health*, April, 1914, Vol. IV, No. 4, p. 289.

<sup>36</sup> Wagener (Monshrift für Kinderheilkunde, xii, 2, p. 477) describes mild catarrhal attacks during epidemics in adults who have had measles, and believes these to be atypical cases. He states that the disease is spread by these missed cases.

Adults are susceptible to measles, provided they have not had a previous attack. Susceptibility to the infection does not diminish with increasing age; the disease is apparently one of childhood only on account of the chances of exposure in early life. Before the days of vaccination smallpox was also a disease mainly of childhood.

The following instances demonstrate the susceptibility of adults to measles and also the serious nature of the disease: Measles was introduced into the Faroe Islands in 1846 from Copenhagen, and over 6,000 of the 7,782 inhabitants were stricken. Panum found no natural immunity in this epidemic. In 1775 it was introduced into the Sandwich Islands, and in 4 months 40,000 of the population of 150,000 died. In 1874, Thacombau, the native chief of the Fiji Islands, had measles while on a visit to Sydney. His son and a native attendant sickened on the voyage home, and carried the infection to the islands, with the result that one-fifth of the population (20,000) died. The virulence of measles under these conditions makes us conclude that a certain amount of resistance is acquired by communities in which the disease has prevailed a long time.

Measles is common in army camps, especially among troops enlisted from country districts, who are thus exposed to the infection for the first time. In the World War, measles was a serious cause of disability in our mobilization and training camps. Pneumonia was the common complication, often resulting fatally.

Measles itself is rarely fatal—95 per cent. of the deaths are due to pneumonic infection. In this regard, influenza and measles are alike. Both diseases become malignant when introduced into a population where they have not prevailed for a long time. Measles lowers the resistance to diphtheria, pneumonia, streptococci, tuberculosis and noma; it is a common history for tuberculosis to develop after an attack of measles.

Measles, perhaps more than any other disease, lowers resistance to other infections. Immune bodies diminish or disappear from the blood during and soon after measles. Thus, the tuberculin reaction is in abeyance during and some months after an attack; typhoid agglutinins diminish in the blood. There is a distinct leukopenia.

Nicolle and Conseil attempted to immunize children with the blood serum of convalescents and also with virus. Similar attempts are now being carried out by several investigators. This work is too recent to form a judgment, but the control of measles clearly depends upon a specific prophylactic.

**Resistance of the Virus.**—In general the virus of measles is known to be much less resistant than that of scarlet fever and many other infections. The virus does not live long upon fomites, probably less than 24 hours. The infection is commonly passed directly from person to

person. There is practically no danger of children contracting the infection from the room in which the patient was treated, even though no disinfection was practiced, provided two weeks have elapsed.

Goldberger and Anderson<sup>37</sup> found, as the result of experiments upon monkeys, that the virus in measles' blood may pass through a Berkefeld filter. In blood serum it resists desiccation for 25½ hours, loses its infectivity after 15 minutes at 55° C., resists freezing for 25 hours, and possibly retains some infectivity after 24 hours at 15° C.

From the standpoint of our present knowledge it is evident that any of the ordinary germicidal agents sufficient to kill spore-free bacteria will serve as effective disinfectants for measles. Aside from the few scientific observations upon the viability of the virus of measles, epidemiological observations have long pointed out the fact that the virus of measles is frail and soon dies in the convalescent as well as in the environment. So far as is known, there are no carriers of measles.

**Modes of Transmission.**—The virus of measles is contained in the nasal and buccal secretions. While it is possible that the virus may leave the body in other secretions, it is highly probable that the discharges from the nose and mouth are the means of transmitting the infection in the vast majority of cases. We are less certain concerning the modes of entrance into the body, although it is presumed that the virus also enters by the mouth and nose. The evidence is clear that measles is usually transmitted by direct contact.

Mayr<sup>38</sup> showed in 1852 by experiments on the human subject that the buccal and nasal secretions were infective. Anderson and Goldberger<sup>39</sup> have demonstrated by experiments upon monkeys that the nasal and buccal secretions of uncomplicated cases of measles may be at times, but are not always, infective. Hektoen<sup>40</sup> in 1905, as well as Goldberger and Anderson, 1911, demonstrated that the virus of measles is also contained in the circulating blood. The virus appears in the blood at least 24 hours before the eruption appears, and begins to diminish about 25 hours after the first appearance of the eruption. Nicolle and Conseil, also Lucas and Prizer have produced experimental measles in monkeys. Blake and Trask's results are convincing.<sup>40a</sup>

It had long been assumed that the virus of measles is carried in the fine bran-like desquamating epithelium, which is one of the characteristics of the disease. Mayr long ago failed in his attempts to inoculate children with measles by using the desquamating epithelium. Anderson and Goldberger also obtained negative results in three experiments, in

<sup>37</sup> *J. A. M. A.*, Vol. LVII, No. 12, Sept. 16, 1911, p. 971.

<sup>38</sup> Mayr, Franz: *Zeitschr. d. k. k. Gesellsch. de Aertze zu Wien*, 1852, I, 13-14.

<sup>39</sup> *J. A. M. A.*, Vol. LVII, Nov. 11, 1911, p. 1612.

<sup>40</sup> Experimental Measles: *Jour. Infect. Dis.*, 1905, Vol. II, p. 238.

<sup>40a</sup> *Jour. Ex. Med.*, March, 1920.

which it was shown that the "scales" were not infective for monkeys. These authorities believe that it is highly probable, if not altogether certain, that the desquamating epithelium of measles in itself does not carry the virus of the disease. This conclusion is warranted by epidemiological evidence.

Measles is so readily communicable that clinicians receive the impression that the virus is "volatile." It has long been suspected that the virus is contained in the expired breath, but this is very doubtful. In fact, it may now be stated with confidence that measles is not air-borne, in the sense in which this term is usually understood. In any case, the radius of danger through the air is confined to the immediate surroundings of the patient—that is, within the danger zone of droplet infection. Droplet infection is quite possible, as the virus is contained in the secretions of the mouth and nose; furthermore, it evidently requires an exceedingly minute quantity of the virus to reproduce the disease in man, who is exquisitely susceptible to this infection.

Chapin has collected important evidence indicating that the infection of measles is not air-borne. Thus, in the Pasteur Hospital, Paris, each patient is cared for in a separate room opening into a common hall. Trained nurses exercise strict medical asepsis. In 2½ years after this hospital was opened in 1900 many cases of smallpox, diphtheria, scarlet fever, and 126 cases of measles were cared for. In no instance did measles spread within the hospital. At the Children's Hospital in Paris (Hôpital des Enfants Malades), instead of being in separate rooms, the beds are separated only by partitions. Strict asepsis is observed. Of 5,017 cases there were only 7 cross-infections, 6 of measles and 1 of diphtheria. Dr. Moizard thinks that this experience proves that even measles is not air-borne, for the few cases of this disease which did arise were not all in cubicles adjoining those occupied by measles patients. Grancher in another Paris hospital had two wards in which there were no partitions, but only wire screens around the beds, simply as a reminder for the nurses. Of 6,541 patients treated from 1890-1900, 115 contracted measles, 7 scarlet fever, and 1 diphtheria. Grancher insists that measles is probably not an air-borne disease. Adjacent patients do not necessarily infect one another. At various other hospitals similar methods have been tried with success. These experiences indicate that the danger of aërial infection in measles is much less than is generally supposed.

The infection of measles is usually transmitted more or less directly from person to person by means of the excretions from the mouth and nose, and most often during the early stages of the disease. Measles may be transmitted by third persons or by fomites only when the time interval is short; such instances are rather exceptional. Carriers are not known.

**Prevention.**—The suppression of measles is one of the most difficult problems we have to face, for the reason that the disease is one of the most highly communicable of all infections, and for the further reason that it is most contagious during the preëruptive stage. To the student of preventive medicine the problem of measles is very similar to that of smallpox and influenza, and the final control will probably have to await a specific prophylactic measure. Improved sanitation, better hygiene, and the general advance of civilization, which have made such a marked impression upon typhus fever, relapsing fever, typhoid fever, and other “filth” diseases, have no influence whatever upon such infections as measles, smallpox or influenza.

Measles is such a common disease that parents are prone to take little pains to avoid the infection; they even sometimes purposely expose their children. This is a mistaken attitude. Special care should be exercised especially during the first five years of life, as over 90 per cent. of the fatal cases occur in this period. While it may be almost hopeless to lessen the morbidity in measles, it is quite possible materially to decrease the mortality by simply delaying the age incidence.

Clinical experience plainly indicates that few people die of measles if properly cared for. The mortality may, therefore, be decreased by careful nursing and protection, especially from streptococci and pneumococci, which are the cause of the most dangerous complications. Newman sums up the matter of prophylaxis when he states that “the prevention and control of measles, like that of whooping-cough and tuberculosis, is largely in the hands of the public themselves.”

In the present state of our knowledge the prophylaxis of measles rests almost entirely upon one measure—isolation. Koplik spots are valuable signs to detect cases early. They appear two or three days, and sometimes six days before the rash. Exposed persons may be quarantined or watched fourteen days. Chapin believes that isolation has been a failure in measles. This is because of the unrecognized but infectious preëruptive stage. “No amount of isolation after the disease is recognized can atone for the harm done before the diagnosis is made.” Isolation, however, accomplishes one worthy object, viz., the prevention of further damage. Isolation, as carried out in our large cities, has had no apparent effect upon the prevalence of the disease. In Aberdeen, restrictive measures apparently protected only 7 to 10 per cent. of the population.

Despite its limitations, isolation is quite worth while. Cases should be at once reported to the health officer, the house placarded, and visiting prohibited. Quarantine should not be raised nor should the child be permitted to return to school until the manifestations of the disease have disappeared. Home treatment with individual care gives the patient the best chance of recovery. Herman advises against sending chil-

dren having measles to the hospital on account of the danger of cross-infection. It is difficult under ordinary circumstances to prevent the spread of the disease to the other children in a household. If the case is treated at home, the children who have not had the disease may be sent away, but kept under observation and also under conditions that will not endanger other children in case the disease develops.

Measles patients must be carefully protected against common colds, diphtheria, pneumonia, streptococcal and other infections; also against exposure and other depressing influences.

Mild atypical and unrecognized cases of measles occur, but are far less numerous than such cases in scarlet fever, diphtheria, and typhoid. Clinical evidence points to the fact that "carriers" of measles do not occur. The disease is usually spread directly from person to person, rarely indirectly through a third person, or by fomites. When measles is conveyed by a third person or by fomites it is by means of contamination with the fresh buccal, nasal, or bronchial secretions upon the hands, handkerchief, or some other object that comes in contact with the mouth or nostrils of a susceptible child. Physicians may readily avoid this danger by wearing a gown and carefully washing the hands, face, and hair, and waiting a reasonable time before visiting healthy children.

Terminal fumigation is of no value in preventing the spread of measles. After the patient is released from isolation a general cleaning with boiling of fabrics should be practiced, especially if healthy children are soon to occupy the playroom or bedroom. However, if from 2 to 3 weeks have elapsed, there is practically no danger in a well-ventilated, sunny, and clean room. All bedding, towels, handkerchiefs, and other fabrics that have been exposed should be boiled or otherwise disinfected. Terminal fumigation for measles has been given up in New York and other cities as unnecessary.

Closing the schools has little effect in preventing the spread of measles. If the school is closed at the beginning of an outbreak and the disease continues to spread after two weeks, little more will be gained in keeping the school closed, for it must then be evident that other factors are at work in spreading the infection. As the disease is mainly spread in the preëruptive stage, it is sufficient to examine the children each morning *before* they enter school for symptoms of a cold, injection of the eyes, running at the nose, cough, sore throat, fever, but especially for Koplik spots. All such cases should be sent home to await further developments.

McVail suggests that when a child develops measles all the children exposed may be allowed to continue at school 8 or 10 days, and then excluded for a week to ten days, when those who do not develop the disease may be allowed to return. This is a rational plan used in certain

districts in England. When measles breaks out in an orphan asylum, a public institution, or an encampment, the only chance of checking the spread of the disease is through the early recognition of first symptom and isolation.

### GERMAN MEASLES

(*Rubella, Rötheln*)

German measles is a distinct disease. It is usually mild and without special complications. It is distinguished from measles by the absence of Koplik spots, the slightness of the prodromal symptoms, the mildness or absence of fever, the more diffuse character of the rash, its rose red color and the early enlargement of the cervical glands. The incubation period is longer than in measles—14 to 21 days, average 17. The two diseases do not protect against each other. German measles is very communicable and extensive epidemics occur.

The cause of German measles is not known. Prevention is the same as for measles.

Clement Dukes described two forms of German measles, one of which he considers a distinct disease somewhat resembling mild scarlet fever, rather than measles. It goes by the name of Dukes' disease, or "the fourth disease."

### SCARLET FEVER

Scarlet fever is an acute febrile infection characterized by a diffuse eruption which appears during the first day or two of the fever, and sore throat of variable intensity. The seasonal prevalence of scarlet fever resembles that of diphtheria. The disease increases in the fall of the year, and continues high until May; there is a sharp drop in June and the curve is low during the hot months of July and August. The period of incubation is from 2 to 7 days; usually 3 to 4. In a few instances, in which individuals have been inoculated with the blood of scarlet fever patients, 3 to 4 days elapsed before the onset of symptoms. For public health purposes the maximum period of incubation is placed at 8 days. Scarlet fever is rare in the tropics; when introduced it soon dies out. There is probably always more or less scarlet fever in every thickly settled district in the temperate zone. The infection is kept alive largely through the mild and unrecognized cases. Scarlet fever varies greatly in intensity in different outbreaks. In some epidemics the death rate is 30 per cent.; in others it is practically nil. In recent years the disease is distinctly milder than formerly.

Landsteiner, Levaditi and Prasek <sup>41</sup> apparently succeeded in transfer-

<sup>41</sup> *Ann. de l'Inst. Pasteur*, Oct., 1911, XXV, No. 10, p. 754.

ring scarlet fever to chimpanzees and also to monkeys. The animals were inoculated both by applying throat swabs from scarlet fever patients to the pharynx of the animals, and also by injecting the animals with blood from scarlet fever patients. While the nature of the virus is still unknown, it seems to be present in the tonsils, tongue, blood, lymph nodes, and pericardial fluid.

The cause of scarlet fever is not known. Mallory and Medlar<sup>42</sup> described a small bacillus (*B. scarlatinae*) in the mucous membrane of the tonsils and throat and upper respiratory passages in the early stages of the disease, which has since been identified as *B. bronchisepticus*. Streptococci are almost constantly found in the throat and blood of scarlet fever cases. Klein in 1885 was the first to advocate the *Streptococcus scarlatinae* as the specific cause of scarlet fever. Kurth assigns an etiological factor to the *Streptococcus conglomeratus*. It is said to produce a rash in animals and men who are injected with it. Streptococci of the beta type described by Theobald Smith are the pathogenic type frequently found in scarlet fever. The chief reasons for considering streptococci as the cause of scarlet fever are that they are constantly found in the throat of scarlet fever patients; that frequently they can be isolated from the blood of scarlet fever patients during life, and almost constantly after death; and that they are the cause of the complications and death in the majority of cases of scarlet fever. It is probable, however, that streptococci play a secondary rôle in scarlet fever as they do in smallpox; the disease itself may be due to a virus, which lowers resistance to streptococcal invasion.

It is clinically impossible to distinguish some cases of septic sore throat from scarlet fever.

**Modes of Transmission.**—It is taken for granted that the virus of scarlet fever is contained in the secretions from the nose, throat, and respiratory tract. The virus probably enters by the mouth and respiratory passages. It is commonly stated that scarlet fever is not contagious during the period of incubation; little, if any, during the period of invasion, and most contagious during the period of eruption. The contagiousness depends upon the discharge of the virus, which in turn depends upon the condition of the mucous membranes of the nose and throat. This varies in different cases, but as the catarrhal symptoms are usually most pronounced during the time of the rash this is therefore the time of greatest danger in the average case. Scarlet fever may be communicable from the beginning of mucous membrane lesions until long after convalescence. Scarlet fever is readily communicable, but less so than measles or smallpox; it ranks about with diphtheria.

Scarlet fever is mainly spread by contact, carriers and milk.

It has long been accepted and taught by the medical profession

<sup>42</sup> *Journal of Medical Research*, March, 1916, Vol. XXXIV, No. 1, pp. 127-130.

that the desquamation is the most infectious stage of scarlet fever, and it is now very difficult to unteach the public this erroneous view. It is now known that desquamating patients may, as a rule, be safely released from quarantine in the 6th week of their attack of scarlet fever, provided they have no mucous complications or other sequelae. Convalescents may be a source of danger to others even after desquamation has ceased. This fact has been emphasized from a study of the so-called "return cases." Thus convalescents are released from hospital and permitted to return home; soon another case appears in one of the members of the household, who in turn comes to the hospital. Neech in a study of 15,000 cases found that the percentage of return cases was 1.86 in those cases who submitted to an average period of isolation of 49 days or under. With an average period of 50 to 56 days the percentage was 1.12; where the isolation extended to between 57 and 65 days the percentage of return cases was 1. McCollom states that in the South Department of the City Hospital, Boston, the children are kept 50 days, and no patient is released who has a discharge from the nose or an abnormal condition of the throat; nevertheless of 3,000 patients discharged from the scarlet fever ward, 1.7 per cent. of return cases occurred.

There is no accurate means of determining just how long a child remains infective after scarlet fever. The period of detention varies very much. Fifty days may be taken as a working average. In New Haven and Seattle cases are dismissed after desquamation; in North Dakota 5 days after desquamation; in Ohio and South Dakota 10 days after desquamation. In various cities and states the period of isolation varies from 3 weeks to 8 weeks unless the physician certifies that desquamation has ceased. In Milwaukee, Paterson, and Pittsburgh it is never maintained longer than 30 days, even if desquamation continues. Owing to our lack of knowledge on the subject, the period of isolation must remain more or less guesswork. An unduly long detention is a hardship upon the patient and the family; on the other hand, a scant period is hazardous to the community. Cases with rhinorrhea, otorrhea, throat trouble, or discharging abscesses must receive special care, as the secretions from these parts are now known to remain infective for a long time. Any unhealed area of the body surface either cutaneous or mucous may discharge the virus.

Many cases of walking scarlet fever present little further evidence than a passing sore throat. These cases doubtless spread the disease by contact. Third persons may carry the virus perhaps on their person and perhaps also as carriers. Toys, cups, spoons, pencils, chewing gum, candy, drinking glasses, thermometers, handkerchiefs, and other objects contaminated by the secretions of the mouth play the same rôle here that they do in diphtheria. Scarlet fever is not air-borne; at least the radius of infection is limited to droplet infection.

Direct contact is the most important and most frequent method of transmitting scarlet fever.<sup>43</sup> The susceptibility is indicated by the fact that less than 3 per cent. of the nurses at the South Department (Boston City Hospital) contract the disease; and only a small fraction of a per cent. of medical students. Place believes that a large majority of people, probably 75 per cent., escape scarlet fever.

*Milk-borne Scarlet Fever.*—Milk is a rather frequent vehicle for scarlet fever infection. The milk is practically always contaminated from human sources. There is, however, some suspicion that streptococcal diseases of the cow may in some instances be identical with scarlet fever. This is doubtful. It is believed, however, that some diseases of the udders of the cows may cause outbreaks of an infection resembling scarlet fever. Trask collected 51 scarlet fever epidemics reported as spread by milk. Twenty-five of these occurred in the United States and 26 in Great Britain. In 35 of the epidemics a case of scarlet fever was found at the producing farm, the distributing dairy, or milkshop at such a time as to have been the possible source of infection; in 3 of the outbreaks the bottles returned from infected households and refilled without previous sterilization were given as the source of infection; in 3 of the outbreaks scarlet fever persons handled the milk or milk utensils, and in 12 of the outbreaks the cows were milked by persons having scarlet fever; in one epidemic the same person nursed the sick and handled the milk; in 2 of the outbreaks the source of infection was supposed to be due to disease of the cow. A milk-borne outbreak in Washington was traced to a convalescent with a discharging ulcer on the finger. Milk-borne outbreaks of scarlet fever are sometimes very extensive.

An unusually extensive milk-borne outbreak of scarlet fever occurred in Boston during April and May, 1910. A total of 842 cases were reported from Boston and the surrounding towns of Chelsea, Winthrop, Cambridge, Somerville, Malden, and Everett. Investigation showed that most of the cases occurred on the route of a large milk contractor. Of the 409 cases in Boston, 286, or nearly 70 per cent., were on the route of this dealer; while 123, or 30 per cent., used other milk. Of the 155 cases that occurred in Cambridge, 126, or over 80 per cent., were on the route of the same dealer. About the same proportion of the cases in the other cities used the milk of this dealer. The cases appeared suddenly April 25th, and the outbreak ceased May 7th. The epidemic reached its highest mark on April 29th, when 128 cases were reported. The indications were plain that the outbreak was the result of more than a single infection. The milk was pasteurized at 60° C. for 30 minutes on April 27th, and three days following there was a notable and sharp decline in the number of cases. The source of the infection could not be traced, although it probably consisted of a "missed" case on one of

<sup>43</sup> Kobrak, *Zeitschr. f. Kinderheilkunde*, Aug. 16, 1920, p. 137.

the 250 dairy farms from which the dealer obtained this particular supply of milk.

**Immunity.**—One attack of scarlet fever usually protects against subsequent attacks. In rare instances second attacks may occur after an interval of several years. Children under 10 are most susceptible. Sucklings are rarely attacked, though susceptible. After the 10th year the resistance to the disease increases. Ninety per cent. of the fatal cases occur in children under 10 years old. The reason why infants at the breast are less likely to take the disease may be on account of the diminished chances of the infection entering the mouth. The immunity acquired in later life may in part be due to previous unrecognized mild attacks. Family susceptibility occurs.

**Prophylaxis.**—Prophylaxis in scarlet fever must necessarily be in excess of the requirements, awaiting more precise knowledge of its cause and modes of transmission. The essential features of prevention consist in isolation and disinfection. It is important to recognize the mild cases in schools through an efficient medical inspection. The answer to the question whether schools should be closed when scarlet fever breaks out varies with the circumstances. In country districts this is advisable, as the children may be kept separate, but in the cities little is gained. Better results may often be achieved by daily inspection of all pupils than by closing the school. All members of the household, where a person is ill with scarlet fever, should be excluded from school until one week has expired from the last possible exposure, unless immunized by a previous attack of the disease. All other members of the household may be allowed to continue their usual occupations except those engaged in handling milk. Patients with scarlet fever should be cared for in hospital. There is no objection to treating a case of scarlet fever in the household, provided a suitable room and trained attendant may be had. The infection may be confined to the sick room, but it is preferable to take no chances and send the susceptible individuals out of the house. The nurse should use the precautions described for diphtheria, smallpox, or measles. The physician should wear a gown and thoroughly disinfect his hands and other exposed parts after the visit. Special care must be taken with the thermometer and other instruments. The physician may find the necessary precautions and disinfection to be irksome, but they should not be shirked in justice to his other patients and the community.

The discharges from the mouth, nose, and respiratory passages, etc., should be collected upon suitable fabrics and burned. Bed and body clothing, dishes, and other exposed objects must be disinfected. Care must be taken concerning remnants of food from the sick room.

Scarlet fever is not as highly contagious as measles, but the measures employed should be practically the same until at least we have more definite knowledge concerning the channels of entrance and exit

of the virus and its modes of transmission. The virus of scarlet fever is more resistant than that of measles. It clings persistently to clothing and various objects. A terminal fumigation with formaldehyde gas may be practiced, although little seems to be gained thereby. A thorough cleansing of all surfaces, with a good sunning and airing of the room, is always in order. All fabrics and other objects that have been exposed should be disinfected. The virus is killed with agents that destroy non-spore-bearing bacteria. In Glasgow a sanitary wash-house has been established, where the clothing of scarlet fever cases may be disinfected and washed. This is a commendable example that might be followed with advantage by other cities. The prevention of nephritis, which is a frequent and serious sequel of scarlet fever, consists in absolute rest in bed for four weeks even in the mildest cases, and a low protein diet—chiefly bread and milk.

*Specific Prophylaxis.*—Attempts at artificial immunity by inoculation have failed because the inoculated disease does not prove milder, as in the case of smallpox. Whether immunity may be secured through general hygiene is doubtful, although good care of the teeth and gums, normal tonsils and healthy mucous membranes of the throat may afford some protection.

Gabritschewsky first proposed the use of streptococcus vaccines as a prophylaxis against scarlet fever. The results of streptococcal vaccines in Russia indicate that vaccinated persons contract the disease in from 0 to 8.5 per cent. in different villages as contrasted with 13.3 per cent. to 70.6 per cent. in unvaccinated. Of ninety-one unvaccinated persons reported by Smirnoff, 37.3 per cent. developed scarlet fever as contrasted with 3.93 per cent. of 127 vaccinated. The value of these vaccines for scarlet fever needs confirmation and until more evidence is obtained we must remain skeptical as to their prophylactic value.

Moser's polyvalent antistreptococcus serum has been used in the treatment of the disease, but has not been advocated as a prophylactic.

## WHOOPIING-COUGH

(*Pertussis*)

Whooping-cough occurs in epidemics, which vary greatly in virulence, intensity, and mortality. The disease is more frequent and severe in cold climates; otherwise uninfluenced by season and weather.<sup>44</sup> The cause of whooping-cough is a small bacillus, described by Bordet and Gengou, recognized by agglutination and complement fixation tests.<sup>45</sup>

<sup>44</sup> In New York, most cases during the past 10 years occurred during the spring and summer.

<sup>45</sup> *Ann. de l'Inst. Pasteur*, Vol. XX, 1906, p. 731.

This bacillus is found most readily in the beginning of the disease, in the matter from the depths of the bronchi brought up during the paroxysms. In this exudate, which is white, thick, and rich in leukocytes, the bacilli exist in considerable numbers and sometimes in almost pure culture.

In the early catarrhal stages it is difficult to obtain sputum. The bacillus can be isolated by holding a Petri dish with suitable medium close to the child's mouth while coughing. It is rare to find the Bordet-Gengou bacillus after the fourth week.

**Mode of Transmission.**—Whooping-cough is usually transmitted directly from person to person in the same ways that diphtheria and other infections contained in the secretions of the mouth and nose are spread. Handkerchiefs, toys, drinking cups, roller towels, and other objects recently contaminated with the infective secretions may act as vectors. It is also transmitted by droplet infection, kissing and close contact. In 60 per cent. of the cases studied in New York, the source of infection was given as coming from a neighbor (Luttinger).<sup>46</sup> Parents are prone to contract the disease from their children.

Jahn and others called attention to the fact that domestic animals may be affected by whooping-cough, and that they may be the means of transmitting it to children. Coughs of a paroxysmal nature have been observed in dogs, and also in cats. Klimenco<sup>47</sup> and Fraenkel<sup>48</sup> were able to produce what seemed like typical pertussis in monkeys, and Inabo<sup>49</sup> showed that injection of the bacillus in an ape gave rise to a typical whooping-cough with an incubation period of 13 days. Kittens and puppies do not take the disease under ordinary circumstances and for practical purposes of prevention are usually disregarded. Mallory and Horner<sup>50</sup> have shown that masses of *B. bronchisepticus* are found in the superficial layer of the trachea, thereby mechanically paralyzing the cilia. Some of the whooping-cough of animals may be confused with this infection, for the two organisms resemble each other closely (Ferry and Noble).<sup>51</sup>

Whooping-cough is apparently not contagious during the period of incubation, but is communicable from the appearance of the first symptom, and is most contagious during the early stage before the whoop develops. It may be transmitted in the late stages and after convalescence. While the virus is known to be in the secretions from the respiratory tract, all secretions from the mouth and nose (including vomitus) must be regarded as infective.

<sup>46</sup> Bull. No. 49, Dept. of Health, N. Y. City, Sept., 1916.

<sup>47</sup> Centralbl. f. Bakteriol., 1908, XLVIII, 64.

<sup>48</sup> München. med. Wochenschr., 1908, LV, 1683.

<sup>49</sup> Ztschr. f. Kinderh., June 15, 1912.

<sup>50</sup> Jour. Med. Res., Nov., 1912, XXVII, 2, p. 115.

<sup>51</sup> Jour. Bact., May, 1918, p. 192

**Immunity.**—There is no natural immunity to whooping-cough; all are susceptible. Whooping-cough at one time or another affects almost every member of a community and causes 10,000 or more deaths yearly in this country alone. The greatest susceptibility is between 6 months to 5 years. After 5 years the susceptibility decreases with age. One attack confers a definite and prolonged immunity; second attacks are rare.

There is a higher incidence and mortality among girls (56 per cent.) than boys (44 per cent.). Whooping-cough is the only communicable disease of childhood that shows this peculiarity.

The death rate for whooping-cough in the United States in 1917 was 10.4 per 100,000.

**Prevention.**—The incubation is probably 2 to 3 weeks, but the time is indefinite, owing to vagueness of the onset of symptoms. If 16 days have passed without symptoms the danger may be considered as having passed. For practical purposes of prevention 14 days will cover most cases. The long-drawn-out nature of the disease, the difficulty of diagnosis in the early stages when it is most contagious, and the fact that patients sometimes continue to spread the infection for 4 to 6 weeks after apparent recovery, make the control of whooping-cough an exceedingly difficult problem. Hence, with whooping-cough we have the same difficult problem that confronts us in the prevention of measles. Effective measures must await specific prophylactic methods.

Whooping-cough should be reported, houses placarded, and the patient isolated, but the isolation in this case need not include strict confinement to a room. This, in fact, may be an unnecessary hardship to the patient, who does better out of doors. If the patient is permitted to take the air, he must avoid contact with his fellowmen and not go to school, theater, church, public assemblies, nor ride in street cars or public vehicles. Children should go out only when accompanied by an intelligent caretaker as a protection to others. It has been suggested that children with whooping-cough who are permitted their liberty should be plainly labeled with a red cross on their arm, or a yellow flag, or the word "whooping-cough" conspicuously displayed on their clothing, to serve as a warning to others. Children who have been exposed should be isolated as soon as they show catarrhal symptoms or begin to cough, not waiting for the characteristic spasmodic whoop. Each community should provide a hospital-farm for children with whooping-cough who lack proper care.

Early diagnosis and prompt reporting of cases are essential. Other catarrhal diseases may cause paroxysmal cough, hence a positive diagnosis can only be made from cultures. Luttinger states that only about 10 per cent. of the cases of whooping-cough in New York City are reported. The disease is most communicable during the catarrhal or early

stages, when the infection can be recognized only by bacteriological methods.

Patients should not be released from quarantine until at least 4 weeks have elapsed after the onset of symptoms. The duration of isolation varies in different cities; thus it is 6 weeks in Montclair, N. J.; on recovery in Providence; as long as the cough lasts in Boston. In Michigan the disease is considered infectious 3 weeks before the whoop and 4 to 6 weeks after apparent recovery. The Danish regulations permit release from quarantine after four weeks and two negative cultures.<sup>52</sup> The State Board of Health of Michigan requires disinfection of the clothing and premises before the patient is released, and forbids public funerals in deaths from whooping-cough.

Individual prophylaxis consists in avoiding the infection. The greatest care in this regard should be taken with children before the age of 5 years. Ninety-six per cent. of the 6,324 deaths from whooping-cough in the United States in 1906 were in children under 5 years of age. Dogs, cats, and other domestic animals should be kept away from the patient, and the possibility of conveying the disease in this way must be guarded against in the susceptible.

The Bordet-Gengou bacillus is frail and soon dies in the environment; therefore, terminal fumigation of the room is not necessary, although cleaning and airing of the premises are in order. Handkerchiefs, fabrics, toys, and other objects that have come in contact with the secretions from the mouth and nose should be boiled or saturated with a strong germicidal solution. The sputum and vomitus should be burned or disinfected as for tuberculosis.

Mild, abortive, and missed cases spread the infection. Most cases of whooping-cough, however, give a clear history of recent contact with another case.

Whooping-cough usually runs a favorable course in healthy children over five years old, and after puberty it is rarely fatal. The most important thing then is to keep babies and young children from having the disease. Delaying the age incidence will materially decrease the mortality. Particular care should be taken during and for several months following convalescence to prevent the development of tuberculosis.

Schools need not be closed on account of whooping-cough. Daily inspection of pupils may achieve better results. The well children of a household, where a person is ill with whooping-cough, should be excluded from schools unless they have had the disease or until two weeks have elapsed since the last exposure, and then only provided they are free from catarrhal symptoms. Other members of the household may be allowed to follow their usual occupations.

Hess and others have recently used vaccines of the Bordet-Gengou

<sup>52</sup> Chievitz and Meyer: *Ann. de l'Inst. Pasteur*, 1916, 30, p. 503.

bacillus as a prophylactic with seeming success. The evidence so far shows no striking protective power of these vaccines. The immunity produced is slight if any. The subject is being studied.

The control of whooping-cough is a matter which is largely in the hands of the public itself. The dangerous nature of this infection should be emphasized, and people taught that it is contagious both before and after the "whoop." Mild cases which do not have the characteristic whoop spread the disease; this is especially common in adults.

**Mortality.**—The dangerous nature of whooping-cough is not generally realized. Whooping-cough almost everywhere causes more deaths than scarlet fever. Many deaths registered as bronchitis and bronchopneumonia are secondary to whooping-cough; during the summer, gastro-intestinal complications are serious in young children. In the United States in 1910 the death rate per 100,000 was as follows: Whooping-cough 11.4; scarlet fever 11.6; measles 12.3; and diphtheria 21.4. In Glasgow the annual mortality from whooping-cough for 40 years, 1855-1894, was 13.5 per hundred thousand inhabitants, and exceeded that from any other acute communicable disease. In England and Wales in 1891 more deaths occurred from whooping-cough than from measles, diphtheria, scarlet fever, or typhoid fever. The mortality figures would be still higher if all the deaths directly or indirectly due to it were completely reported, for the fatal termination is usually due to complications and sequelae which occur in one-fourth to one-third of all cases. As a result of these complications the original disease is frequently lost sight of entirely in the vital statistics. According to Farr's law—that contagious diseases increase as density of population increases—the death rate from whooping-cough in our country will undoubtedly increase in our more sparsely settled states with increasing population and rapidly extending lines of railroad and other facilities, and with easy, frequent, and rapid movements of the people.

The gravity of whooping-cough is scarcely appreciated, either by the physician or the public, and there is much heedless neglect with reference to the prevention of this infection.

## MUMPS

*(Epidemic Parotitis)*

Mumps usually occurs between the ages of 5 to 15 years. There is decreased susceptibility both before and after this time. It is a disease of children and young adults. As a military problem, mumps frequently occurs in men between 21 and 31 years. In the soldier and sailor the infection is dreaded because it is disabling and unmanageable. In 1918, there were 5,756 cases of mumps among 18,000 men at Camp Wheeler,

an incidence of 32 per cent. One attack usually confers immunity, but second attacks occur, and third attacks are sometimes reported. The disease may occur as epidemics in civil institutions and military establishments, which usually develop slowly and last a long time. It is difficult to trace and eradicate. Orchitis is a frequent and painful complication and when both testicles are involved may cause sterility. Other complications are: great prostration; a tendency to develop mania, or wild delirium, or a comatose state resembling uremia; meningism, mastitis, otitis media, tonsillitis, and pneumonia also occur. Mumps is contagious before the symptoms appear, and for some time, even 6 weeks, after symptoms have disappeared. It is probably transmissible as long as the glands are swollen. The parotids are most frequently involved, next the submaxillary, and last the sublingual. The lachrymal glands escape. The disease is usually spread by direct contact; rarely by indirect contact or by a third person. It is not air-borne. The virus is contained in the secretions from the mouth and perhaps the nose. The incubation is variously stated at from 4 to 25 days; it is variable and sometimes prolonged. For public health purposes the maximum period of incubation is placed at 21 days.

Granata in 1908, and Nicolle and Conseil<sup>53</sup> in 1913 obtained indications that mumps may be due to a filterable virus; Martha Wollstein<sup>54</sup> in 1918 showed that the salivary secretion in mumps contains a virus, which when filtered and injected into the parotid glands and testicles of cats, causes pathological changes resembling mumps in human beings.

The virus is detected most readily in the saliva during the first three days of the disease, less easily on the 6th, and not at all on the 9th day. It is also present in the blood of patients showing marked constitutional symptoms, but not in the cerebrospinal fluid.

Mumps is required to be reported in Maryland, Grand Rapids, and Raleigh, and placarded in Cleveland. Prevention depends upon the usual practice of isolation and disinfection.

Hess<sup>55</sup> injected 6 to 8 c. c. of blood of convalescents intramuscularly into 17 children. None of these children developed mumps, although exposed to it in an institution where the disease was epidemic. If confirmed, this procedure could be made use of in the home as well as in institutions.

Orchitis occurs as a complication in as high as 25 per cent. of the cases. It is rare before puberty. There is some support for the old suggestion that the infection is conveyed to the testicles by hand-urethral inoculation, but more likely the virus is brought to the testicles by the blood stream. Traumatism of the testicles predisposes to orchitis, hence

<sup>55</sup> *Proceed. Soc. f. Exp. Biol. and Med.*, Apr. 21, 1915, XII, 7, p. 144.

injurious palpation and injuries however slight should be avoided. Rest in bed is also a prevention.

### LOBAR PNEUMONIA

Lobar pneumonia is a communicable disease which should be classified with the infectious fevers. If pneumonia were a new disease it would be regarded as "contagious," and its spread would be guarded against by isolation and the application of antiseptic principles. Many different infections are caused by the pneumococcus, but here we will consider only the specific self-limiting disease associated with involvements of one or more lobes of the lung, known as fibrinous, lobar, or croupous pneumonia—also lung fever. The pneumonia considered in this article is an acute, self-limiting, febrile disease caused by one of the pneumococci. The pneumococcus is the common cause of pneumonia, but pneumonitis may also be caused by a long list of other pathogenic microorganisms, such as streptococci, influenza bacilli, Friedländer's bacilli, plague bacilli, typhoid bacilli, etc. A pneumonic condition of the lung is also a frequent terminal state, especially in the young and in the old. Owing to these facts, there is much confusion in the literature as well as in the morbidity and mortality records concerning pneumonia.

The pneumococcus is found not alone in the local lung lesions, but also invades the blood. When this happens in large numbers it increases the severity of the disease. The pneumococcus has a capsule and is soluble in bile. It also gives specific, immunity reactions, especially agglutination and precipitin tests.

Pneumonia is one of the most prevalent and fatal of all acute diseases. As a cause of death it rivals and sometimes exceeds tuberculosis. According to the U. S. Census of 1890, over 9 per cent. of all deaths were due to pneumonia, 10.2 per cent. in 1900, 9.8 per cent. in 1910, and 9.7 per cent. in 1915. The death rate varies. In the United States it was 127 per 100,000 in 1914, and 149.8 in 1917 and still higher during the influenza pandemic of 1918-19. Pneumonia is probably on the increase, owing to factors favoring the spread of the infection, especially crowding; and also to certain devitalizing influences of modern life which heighten susceptibility to the disease; further, more persons are now saved from the acute and fatal infections of childhood and adolescence to become victims of pneumonia later in life.

Pneumonia occurs in all *climates*: it is prevalent in tropical as well as in cold countries. Like other communicable infections, it shows geographic differences: thus, it is more virulent in the United States than in England. This is said to be due to the dry, overheated air of our homes, offices and work rooms.

Pneumonia shows a distinct *seasonal prevalence*: it is most frequent in the winter and spring months. This is not necessarily accounted for by the chilling effects of cold moist air, for Greenberg has shown that a low relative humidity is conducive to a high death rate.<sup>56</sup> Cold, wetting and chilling are generally regarded as important predisposing causes. They may favor autoinfection through inspiration, or may lower the resistance of the bronchial and pulmonary tissues. Fatigue, or some unusual exertion, also plays a part here. Pneumonia is often preceded by an ordinary catarrhal inflammation. Cold and crowding also favors the spread of other respiratory infections, such as pneumonic plague, common colds, sore throats, etc.

Pneumonia is fatal among negroes to a greater extent than among whites; and is more frequent in males. It attacks all ages. The incidence is marked at both extremes of life. It is common in children under six years; between the sixth and fifteenth year the predisposition is less marked, but for each subsequent decade it increases. The relation to age is well shown in the United States Census Report for 1900. The death rate from pneumonia in persons from 15 to 45 years was 100.5 per 100,000 population; from 45 to 65 years, it was 263.12; and in persons 65 years and over it was 733.77! Osler says, "Pneumonia may well be called the friend of the aged. Taken off by it in an acute, short, not often painful illness, the old escape those 'cold gradations of decay' that make the last stage of all so distressing." Pneumonia often attacks the strong and robust in early adult life, but under these circumstances the chances of recovery are good.

**Types of Pneumococci.**—Four groups or types of pneumococci are now recognized, based upon immunological reactions. In three of the groups these reactions are fixed and specific. This grouping is important both from the standpoint of treatment and prevention.

- *Group I* is found in about 33 per cent. of all cases of pneumonia, and has a mortality of about 25 to 30 per cent. of cases caused by it. With the use of specific serum the mortality has been reduced to about 6 or 8 per cent. This type of pneumococcus is rarely found except in cases of pneumonia, or in healthy carriers closely associated with cases. Carriers of this type are temporary.

*Group II* is indistinguishable from Group I save by the agglutination reaction. It is found in about 33 per cent. of all cases of pneumonia, and has a mortality of about 25 to 30 per cent. An immune serum has been produced for this group, but it has feeble therapeutic power. Healthy carriers are temporary and infrequent, and only found in persons who have been in contact with cases of Type II pneumonia.

• A number of atypical members of this group are now classified as sub-group II.

<sup>56</sup>J. A. M., Jan. 25, 1919.

*Group III* is the *pneumococcus mucosus*, formerly confused with the *streptococcus mucosus*. These pneumococci are distinguished not only by specific immunological reactions, but by the fact that they have a large capsule, and colonies on solid media form an abundant, sticky, mucoid growth. This type is the cause of about 10 to 15 per cent. of all pneumonia, and is fatal in about 50 to 60 per cent. of cases. While infrequent it is malignant. No therapeutic serum of practical value has been obtained against this type of infection. Healthy carriers occur, but do not give a history of close association with pneumonia.

*Group IV* comprises all pneumococci that do not belong to groups I, II or III. The strains in this group are not specific. They are frequently found in normal mouths. These organisms have a comparatively lower virulence, causing about 20 per cent. of cases, but under certain conditions strains of Group IV may have an exalted virulence as in the Rand miners in South Africa.

These four groups seem quite stable and show no tendency to mutation. The percentage of incidence and death rates naturally varies with time and place; however, the Rockefeller figures given above have been fairly consistent from year to year, and the figures obtained by others have not varied widely from those stated.

The pneumococci of the first two groups caused about 65 per cent. of all cases of pneumonia in the United States, during the years studied. They occurred only in the mouths of people recovering from the disease or of those in direct contact with such cases. From these results, pneumonia was a contact disease in at least 65 per cent. of cases, the infection being obtained from a patient or carrier.

**Resistance of the Virus.**—The pneumococcus is a frail organism; it does not multiply in nature outside of the body and indirect transmission is not likely except with fresh infectious material. Even upon artificial culture media the life of the pneumococcus is brief; it must be transplanted frequently in order to keep it alive; it is customary in laboratories to pass it through a susceptible animal, such as a mouse or rabbit, from time to time, in order to maintain its virulence.

The pneumococcus is readily destroyed by heat; 52° C. for 10 minutes is sufficient. On the other hand, it withstands low temperatures very well. The ordinary germicidal agents destroy it quickly and with certainty. It may live for months in dried sputum, in which it also maintains its virulence. It has been found in the dust of rooms occupied by cases or carriers, and may persist for weeks.

**Modes of Transmission.**—The pneumococcus leaves the body mainly in the discharges from the mouth and nose, and enters the system through the same channels. The infection is spread directly by close personal contact, also indirectly through the great variety of ways discussed under diphtheria and tuberculosis. Indirect transmissions through

cups, fingers, handkerchiefs, and other objects contaminated with fresh discharges may occur; hand-to-mouth and droplet infection also come into consideration.

Pneumonia is spread chiefly by close personal contact with cases or carriers. Carriers of the pneumococci may infect themselves by inspiration. The effect of crowding is well shown by the fact that the disease is more prevalent in cities than in country districts.

Pneumonia occurs in well-marked epidemics. Wells gives an exhaustive tabulation of the epidemics of pneumonia extending back to 1440.<sup>57</sup> Epidemics of pneumonia have occurred in all parts of the world: in Alaska, at Erlangen, Boston, Ireland, Italy, France, Switzerland, and on board ships. The disease has also been observed to spread in hospitals and in houses. The excessive prevalence of pneumonia often found in camps, barracks and among working people, as at Panama and at the African mines, is due to contact infection resulting from crowding of susceptible people.

Pneumonia as a complication of influenza became one of the chief causes of death in our army in the World War. It is quite proper to regard pneumonia as endemic everywhere, with occasional epidemic outbreaks.

The workers of the Rockefeller Institute examined 175 specimens of *dust* from houses with cases of pneumonia due to Type I or Type II. In 75 of these specimens, pneumococci were found, and in 47 they were Type I or Type II, and in all these cases, but two, the type of pneumococcus found in the dust corresponded in type to that isolated from the patient. On the other hand, in 62 specimens of dust obtained from houses in which no cases of pneumonia were known to exist, pneumococci were isolated 18 times, but in only one instance were pneumococci of the fixed Types I or II present, and in this one instance a known carrier of the corresponding fixed type was found to be visiting at the time. Dust transmission is therefore to be feared and measures taken accordingly.

**Carriers.**—Pneumococci are frequently found in the mouths and throats of healthy persons. Sternberg in 1880 first demonstrated a pneumococcus in his own saliva. Netter found it in 20 per cent. of the persons whom he examined, and the New York Commission reported its presence in from 48 to 85 per cent. In other words, the majority of persons seem to be pneumococcus carriers. One fortunate feature of this situation is the fact that practically all the common mouth pneumococci belong to Group IV, which has a low virulence. Pneumococci of Types I and II usually disappear from the mouth within a few weeks after convalescence is established, the longest time so far observed being 83 days. Practically the same facts apply to the persistence of these types

<sup>57</sup> *J. A. M. A.*, Feb. 23, 1889. *Med. News*, May 20, 1905.

of pneumococci in the mouths of healthy carriers. In other words, carriers of these types are temporary, not very numerous, and almost always give a history of recent association with a case of pneumonia.

On the other hand, carriers of Type III and Type IV are very numerous and persistent. Type III is our most severe type of pneumonia, although it occurs only relatively infrequently. Cole found pneumococci of Type III 85 times among 450 healthy carriers. Practically none of these was associated with cases of pneumonia. Moreover, this type may be carried for years.

Stillman<sup>58</sup> found that Type IV predominates in the mouths of healthy individuals, that Type III is fairly frequent, and that atypical organisms of Type II are usually associated with cases of pneumonia, although occasionally it is impossible to trace any such connection. In these cases, it is probable that the pneumococcus was contracted from a carrier or indirectly through cups, spoons, glasses or dust from a case of the disease.

These facts suggest the following conclusions concerning the epidemiology of lobar pneumonia. Infection with pneumococcus of Types I and II must be regarded as dependent upon either direct or indirect contact with a previous case of lobar pneumonia due to the same type of organism. These types of infection are either acquired by direct contact with a previous case of pneumonia, by association with a healthy carrier of one of these types of pneumococcus, or possibly by infection from dust or objects smeared with saliva. Infection with the common sputum-types of pneumococcus, namely Types III and IV, and the atypical strains of Type II, may be autogenic, or brought about by a special susceptible. No known measures will relieve pneumococcus carriers.

Ethylhydrocuprein hydrochlorid has special pneumococcidal activity,<sup>59</sup> and has been recommended to disinfect carriers. Kolmer and Steinfeld<sup>60</sup> recommend a mouth wash and gargle of the following formula:

Ethylhydrocuprein hydrochlorid (or quinin bisulphid)	.005 gm.
Liquor thymolis	5.0 c. c.
Distilled water sufficient to make	50.0 c. c.

**Immunity.**—One attack of pneumonia does not leave an immunity. In fact, one attack predisposes to subsequent attacks, as is the case with erysipelas and rheumatic fever. Man, however, must possess a certain degree of resistance to the pneumococcus, else the disease would be even more prevalent than it is, and recovery would probably be less fre-

<sup>58</sup> *Journ. Exp. Med.*, Dec., 1916, XXIV, 6, 651; also a study of 100 normal individuals by Jacob Myer, *J. A. M. A.*, Nov. 6, 1920, Vol. LXXV, No. 19, p. 1268.

<sup>59</sup> Morgenroth and Levy, *Berlin. klin. Wochenschr.*, 1911, 48.

<sup>60</sup> *J. A. M. A.*, Jan. 5, 1918, Vol. 70, No. 1, p. 14.

quent. Recurrence is more common in pneumonia than in any other acute disease. Instances are on record of individuals who have had 10 or more attacks. Rush gives an instance in which there were 28 attacks.

All kinds of animals, even the most susceptible, may be rendered actively immune to pneumococcus infection by the previous injection of non-lethal doses of living pneumococci, or even by the injection of the dead cocci. The serum of such actively immunized animals, in many cases, possesses protective and even curative power. The chief antibodies which can be demonstrated in this immune serum are agglutinins and opsonins or bacteriotrophins.

The mechanism of the immunity to this infection is not at all understood. Phagocytosis may play a prominent, perhaps a dominant, rôle. Protective antibodies, rather feeble, have been found in the blood serum of immunized animals, and also in the blood serum of persons who have recovered from pneumonia. The pneumococcic attack, especially the crisis, resembles an anaphylactic reaction, and, while the mechanism of immunity in this infection is probably complex, the best explanation of it at present is in terms of anaphylaxis. The immunity is quite specific.

Many weakening diseases diminish resistance to the pneumococcus. Pneumonia is frequent in alcoholics and is commonly brought on by exposure to cold, to trauma, or to local irritation. It is a frequent complication of influenza, measles, whooping-cough, typhoid fever and other infections. Pneumonia often closes the scene in chronic heart disease, pulmonary phthisis, Bright's disease, diabetes and other debilitating affections.

Immaturity and old age, as well as other enfeebling conditions, may act as a predisposing cause by lowering immunity. Other factors which predispose to pneumonia are sudden changes in temperature, trauma, irritation caused by aspiration of foreign substances, or the inhalation of dust or irritating vapors.

It should be remembered that pneumonia, like other communicable infections, frequently attacks the strong and robust.

Fatigue, exposure and overexertion have long been recognized as contributing causes of pneumonia. Fatigue and overexertion favor the inspiration of infectious material into the trachea. Blake and Cecil<sup>61</sup> have produced pneumonia in monkeys simply by injecting small amounts of a pure culture by means of a fine needle into the trachea. Kinyoun and Rosenau, also Meltzer and his colleagues have produced pneumonia by intratracheal insufflation of large amounts into dogs.

The pneumococcus is particularly virulent when it attacks races in

<sup>61</sup> *Jour. Exp. Med.*, Apr. 1, 1920, Vol. XXXI, No. 4, pp. 403, 445; May 1, 1920, No. 5, pp. 499, 519; June 1, 1920, No. 6, pp. 657, 685; July 1, 1920, Vol. XXXII, No. 1, p. 1; Oct. 1, 1920, No. 4, p. 401; Dec. 1, 1920, No. 6, pp. 691, 719.

which the disease has not been prevalent. This was the case with the laborers on the Panama Canal and the miners on the Rand. Such circumstances indicate that a certain amount of racial resistance is acquired through long conflict with the pneumococcus.

**Prevention.**—*Vaccines* are now being tried as a prophylactic against pneumonia. Theoretically, we might expect it to be a hopeless task to produce by artificial methods a useful immunity to a disease which leaves little or no natural immunity; in fact one attack predisposes to recurrences. On the other hand, a high degree of protection can easily be induced in susceptible animals to virulent cultures of pneumococci when injected into the peritoneal cavity, the blood stream, or subcutaneously. The results of preventive inoculation upon man are encouraging, but must await some years of careful observation, with controls, before we know the quality of the protection afforded and the proper vaccine to use.

Following the promising but inexact experiments of Wright in South Africa, Lister<sup>62</sup> carried out prophylactic immunization in a large number of Rand mine workers, using a composite vaccine made from pneumococcus types prevalent in that region. He found that subcutaneous injections protected against the types used in the vaccines.

Cecil and Austin<sup>63</sup> inoculated some 12,000 seasoned troops (20 per cent. of the command) at Camp Upton, with a saline pneumococcus vaccine containing Types I, II and III. Three or four doses were given at weekly intervals, the first containing three billion organisms, and the final doses from six to seven and one-half billions. While the period of observation after the inoculation was only ten weeks, evidence of protection was made apparent by the fact that no cases of pneumonia of Types I, II or III occurred in the vaccinated groups, while 26 cases due to these types originated in the unvaccinated groups. Only 17 cases of pneumonia of all types developed among the vaccinated as contrasted with 172 cases among the unvaccinated men.

Cecil and Vaughan<sup>64</sup> immunized 80 per cent. of the command at Camp Wheeler. The conditions here differed materially from those at Camp Upton in several respects: (1) a larger number of the troops were recruits, and hence more susceptible;<sup>65</sup> (2) the work was complicated by the influenza epidemic; (3) a lipovaccine was substituted for the saline vaccine. This vaccine contained the 3 types of pneumococci in a dosage of 10 billion organisms, and only one injection was required. During a period of three months, 363 cases of pneumonia of all varieties occurred among the men vaccinated (80 per cent. of the command), and 327 cases among the unvaccinated troops (20 per cent. of the command).

<sup>62</sup> So. African Inst. for Med. Research, 10, 1917.

<sup>63</sup> *J. Exper. Med.*, XXVIII, 19, July, 1918.

<sup>64</sup> *Ibid.*, XXIX, 457, 1919.

<sup>65</sup> Opie, E. L., *et al.*: *J. A. M. A.*, 72, 108, Jan. 11, 1919; 72, 556, Feb. 22, 1919.

Only 8 cases of Types I, II, and III developed among the vaccinated men, and these were all secondary to severe cases of influenza. This excellent work in the army could not be followed up, was in a complicated situation, and is therefore not conclusive.

Pneumococcic immunity is strictly specific. Vaccines protect only against the pneumonia caused by those groups represented in the vaccine. Much more work will have to be done before a statement can be made concerning the prophylactic value of these measures. Studies are now being made by a Commission<sup>66</sup> upon groups involving many thousands with equal numbers of controls. The results of this work will not be known for several years. Antipneumococcus serum is useful in the treatment of Type I pneumonia if given early and in sufficient amount, but has no preventive virtues.

**Preventive Measures.**—The prevention of pneumonia is rapidly becoming more definite through a better understanding of the causes of the infection, and the factors which contribute to its spread. We must keep in mind that the disease called pneumonia is a group of closely related infections which may require somewhat different methods of control. In Types I and II, the emphasis must be placed upon direct contact with cases and carriers, and also dust; in Types III and IV, these factors also obtain, but personal prophylaxis to prevent auto-infection may be especially important. Until we have more precise knowledge, our measures should be general enough to include all members of the group.

Man is the source and fountain head of the infection. Each case of pneumonia is a focus for the spread of virulent pneumococci. Isolation and disinfection of discharges are the first indications. Limiting the number of persons who come in contact with the patient will lessen the number of carriers.

Pneumonia should be added to the list of diseases requiring compulsory notification. Cases should be isolated at least in the same sense that diphtheria is isolated—the discharges from the nose and throat should be burned or disinfected. If the patient is treated at home, the house should be placarded in order to discourage visiting and as an educational measure.

Isolation in hospitals may be accomplished by proper nursing technic, including the disinfection of discharges and all objects soiled with the infectious materials, especially fabrics, hands, spoons, cups, thermometers, etc. Sanitary isolation may be favored by the use of cubicles or screens between beds, and also by the use of masks by patient, doctor, nurse and attendants. Hospitals should take active measures to pre-

<sup>66</sup>The Commission for the Study of the Cause and Prevention of Influenza and Pneumonia of the Metropolitan Life Insurance Company, consisting of: Dr. Lee K. Frankel, Dr. A. S. Knight, Dr. W. H. Park, Dr. W. H. Frost, Dr. G. W. McCoy, Dr. E. O. Jordan, and Dr. M. J. Rosenau, Chairman.

vent cross infection and institutional outbreaks. It appears that pneumonia complicating measles, influenza and other diseases is apt to spread in hospitals, unless cases are isolated and guarded with special care.

Crowding, especially of the kind that favors the spread of the buccal flora from mouth to mouth, must be discouraged. Persons who sleep, work and play together, wash from the same bowl and eat with the same tableware, have every opportunity of spreading infections of the upper respiratory tract. This is why pneumonia and other acute infections of the mucous membrane of the upper respiratory tract are common and often epidemic in camps, schools, prisons, institutions, ships and industrial establishments. The factor of crowding and close personal contact needs emphasis and attention.

Upon the Isthmus of Panama pneumonia was unduly prevalent owing to overcrowding, which favors contact infection. The same was found by General Gorgas among the workmen of the African mines. The prevention consisted in scattering the workmen, giving them separate homes in place of barracks. Allaying street dust and house dust removes one of the predisposing causes of pneumonia and other respiratory infections.

As carriers doubtless play an important rôle in disseminating this infection, the education of the public concerning certain sanitary habits should be actively continued. These include the danger of spitting promiscuously and of kissing; the proper care to be exercised in sneezing and coughing; the peril in the common drinking cup, the roller towel; and the habit of placing unnecessary things in the mouth, especially the fingers. Restaurants, hotels and soda fountains should be required to scald all glasses, cups, spoons, etc., every time they are used. Lynch and Cumming<sup>67</sup> emphasize the importance of the sputum-borne diseases through hand to mouth infection and the warm water used to wash mess-kits, and dishes in hotels, restaurants, etc.

It should become common knowledge that anything which tends to reduce vitality predisposes to pneumonia, such as dissipation, loss of sleep, overwork, worry, poor or insufficient food, lack of exercise, alcohol, colds, or excesses of all kinds; the atonic effect of living in overheated rooms, and the injurious effect of excessively dried and warmed air, and sleeping in warmed rooms. Cold baths, regulation of temperature and ventilation, sleeping with open windows or in the open air, as well as oral hygiene, are useful prophylactic measures for pneumonia as well as tuberculosis, "colds," and a large group of diseases.

<sup>67</sup> Lynch, C. C., and Cumming, J. G.: *Military Surgeon*, Dec., 1918; *Am. Jour. Public Health*, Jan., 1919, Vol. IX, No. 1, p. 25; *Jour. Lab. and Clin. Med.*, Vol. V, No. 6; *Military Surgeon*, Oct., 1919.

Cumming, J. G.: *Am. Jour. Public Health*, Nov., 1919, Vol. IX, No. 11, p. 849; *Military Surgeon*, Feb., 1920; *Am. Jour. Public Health*, Nov., 1920, Vol. X, No. 11, p. 849.

A case of pneumonia due to Type I or II should not be released from quarantine until these fixed types have disappeared from the mouth. This is usually only a matter of a few weeks. After the patient is discharged, the room should be given a thorough cleaning with soap and water, and disinfected with one of the germicidal solutions.

Close supervision is needed of the acute respiratory infections such as ordinary "colds," so-called influenza, bronchitis, and sore throats. These catarrhal inflammations are often associated with pneumococci and predispose to pneumonia. Persons suffering with these "minor" infections should be isolated in bed during the acute stage and at least as long as there is fever. Exposure, overexertion, and fatigue under these circumstances may be hazardous.

Health officers may assist by disseminating knowledge concerning the disease, by enforcing antisputting regulations, by proper cleansing and oiling of streets, by requiring a stricter compliance with building and housing laws, and by the regulation of the ventilation and conditions of the air in theaters, schools, street cars, and public buildings, as well as the crowding of such places; also by providing free facilities for laboratory diagnosis, to aid in the search for carriers, to assist diagnosis and serum therapy, and to trace epidemics.

The virulent pneumococcus should not be lightly regarded as a normal inhabitant of the mouth, throat, and nose. Because the pneumococcus is very widely spread and the disease is ubiquitous, and because the associated factors which determine infection seem complicated and not well understood, are not sufficient excuses for a supine and hopeless attitude. The problem of tuberculosis has been attacked with vigor with scarcely better understanding of the fundamental problems at issue. Each case of pneumonia should be regarded as a focus for the spread of the infection. We should think of pneumonia very much as we think of whooping-cough and influenza,—as an infection which is spread from man to man through the secretions of the mouth and nose.

#### INFLUENZA

(*La Grippe—Grip*)

Influenza is an acute, highly communicable, febrile disease, characterized by great pandemic outbreaks. The fever lasts three days and shows a special tendency to bronchial and pneumonic complications. When influenza sweeps over the world in pandemic form, it becomes the

most serious and furious of epidemics on account of the large numbers of people attacked in a short time. There is a high incidence, but a comparatively low case fatality rate, but the mortality is high on account of the great number of cases. Influenza itself probably never kills. Death is always due to some complication, usually pneumonia. Pandemic influenza acts very much like measles in a virgin population.

In the world wide pandemic of 1918-19, it is estimated that there were over 200,000,000 cases and that upwards of 10,000,000 deaths occurred in less than 12 months; in the United States alone there were more than 20,000,000 cases and about 450,000 deaths in less than 6 months. In India, 4,933,132 deaths from influenza were reported from June to November, 1918.

The term influenza has become both popular and vague. It is applied to common colds, acute bronchitis, catarrhal inflammations, nervous indispositions, and brief febrile attacks of unknown origin. Account of an epidemic, probably influenza, was recorded in 1173. Many outbreaks of "plagues," some of them doubtless influenza, occurred long before this. The first authentic outbreak was described in 1510 by the famous physicians Willis and Sydenham. There have been about 80 epidemics, more or less authentic, since 1173. Fourteen pandemics have been recorded since 1510; they are those of 1510, 1557, 1580, 1593, 1729, 1732, 1762, 1788, 1830, 1833, 1836, 1847, 1889 and 1918. The disease appears to have been epidemic in North America in the years 1627, 1647, 1729, 1732, 1737, 1762, 1782, 1789, 1811, 1832, 1850, 1857, 1860, 1874, 1879, 1889-90, 1916 and 1918. The relation of sporadic and inter-epidemic outbreaks to pandemics of influenza is not clear. Scarcely a year passes, particularly during the past century, without news of the epidemic occurrence of influenza at some point or other of the earth's surface.

The cause of influenza is not determined. Filterable viruses have been described<sup>68</sup> and denied.<sup>69</sup> In 1892, Pfeiffer<sup>70</sup> discovered the *Bacillus influenzae*—a small, Gram negative, hemoglobinphilic, frail bacillus. This organism is found in about 30 per cent. of normal throats and is practically always present in measles and whooping-cough. The percentage of times it is found in influenza varies with the observer, many bacteriologists finding it almost constantly in the recent outbreak. The

<sup>70</sup> *Deutsch. med. Wochenschr.*, 2, 1892, p. 28. *Zeitschr. f. Hyg.*, XIII, 1893,

etiological relation to the disease is doubtful<sup>71</sup>—however, the recent experience has greatly raised our respect for Pfeiffer's bacillus, for if it is not the cause of influenza, it may become a virulent secondary invader, and the cause of serious complications. Olitsky and Gates recently cultivated filterable bodies as the cause of influenza.<sup>71a</sup>

**Etiology.**—Influenza is not a clean-cut clinical entity. The manifestations are extraordinarily complex. The fever lasts three days; if prolonged, some complication should be suspected, especially bronchitis or pneumonia. The attack often starts abruptly: hence the term "grip." The prostration is out of all proportion to the fever and lesions. Cough and pains in the head, back and limbs are almost always present. There is a leukopenia. The disease itself is rarely, if every, fatal, death being due almost always to pneumonia. The clinical features of each outbreak vary,—usually the respiratory form predominates. In the 1889-90 epidemic, neuritis and the "nervous form" were common. A gastrointestinal form is described. In the recent pandemic, pneumonic complications were conspicuous and the disease was unusually virulent in pregnant women. The diagnosis of influenza from the clinical standpoint is not trustworthy. There is no criterion by which the infection may be recognized. Until the cause is established, we cannot know the relationship between influenza and the ordinary cases of "catarrhal fever," "grip," common colds, and "influenza colds."

**Mode of Infection.**—It is assumed that the virus leaves the body in the secretions from the mouth and nose, and enters through the same channel. Therefore, it is probable that the infection is contracted through direct and indirect contact and droplet infection. Lynch and Cumming<sup>72</sup> believe that indirect contact and hand to mouth infection are the chief modes of spread. Water, milk, and food are not known to carry the virus. Rosenau, Goldberger and McCoy<sup>73</sup> were not able to transmit the disease to volunteers.

**Epidemiology.**—Influenza attacks all ages and both sexes. During the 1919 pandemic it was most fatal during the age period 20 to 30, and seemed to have a predilection for strong, sturdy, robust young men. More females than males were affected, but the death rate was higher among males. It spares neither class nor race; it takes the rich and poor alike, the strong and the weak, the clean and the dirty. Hygiene and sanitation therefore have practically no effect in controlling diseases like influenza, measles and smallpox.

Influenza occurs as great pandemic waves at irregular intervals of a generation or two. These are followed by years of epidemic and sporadic

<sup>71</sup> *Journ. of Immunology*, Jan., 1921, Vol. VI, No. 1.

<sup>73</sup> Public Health Rpts., 34, No. 2, Jan. 10, 1919; also *Hyg. Lab. Bul.*, U. S. P. H. S., No. 123, Feb., 1921.

prevalence—the etiologic relationship is not established. A pandemic occurs in succeeding waves; the secondary waves are at intervals of 8 months.<sup>74</sup> The entire cycle of a pandemic lasts 4 to 6 years. Epidemics are intermittent and tend to develop periodicity.

When pandemic, the disease attacks 13 to 53 per cent. of the population, averaging about 30 per cent. The incidence on board ship or other limited localities runs as high as 84 per cent.<sup>75</sup> The disease spreads with amazing rapidity. It travels ordinarily from east to west: the 1889-90 pandemic was supposed to start in Russia. Other world-wide epidemics have been traced to the far East. The last pandemic was called Spanish Influenza because it first came to notice in Spain, but probably did not originate there. It started in malignant form in this country in Boston on Commonwealth Pier, then used as a Naval Receiving Ship, in September, 1918, and rapidly spread over the entire country. By November it was difficult to find a community anywhere that was not affected. By January it was on the wane, and by March it had subsided. The duration of an epidemic in any one locality is from 6 to 8 weeks. In compact communities, such as camps, it may run its course in from 4 to 6 weeks. No other disease, except perhaps dengue, attacks such a large proportion of the people in so short a time. Dengue, however, is limited geographically to mosquito centers of warm countries.

Influenza occurs at all *seasons* of the year, with a preference for cold weather. Del Pont, from an historical review of 125 pandemics, shows that 50 occurred in the winter, 35 in the spring, 16 in the summer, and 24 in the fall. It is conveyed by human contact, independent of climate, wind, or weather, except that secondary waves avoid the summer. Epidemics break out with *explosive violence*. This is one of its chief characteristics. The curve is steep-le-like (see chart). Epidemic outbursts of this character usually mean that some common medium is spreading the virus which is infecting a large number of people about the same time. The explosive character of epidemics is explained by the short period of incubation, high degree of communicability of the disease and susceptibility of the population. The rapid spread is further assisted by the fact that many who have the disease do not go to bed, but continue to mingle with their fellow men. Secondary waves in a pandemic cycle are less explosive and the curve is apt to be longer and less symmetrical than the first onrush of a new pandemic. The curve of a primary outbreak is uniform, while secondary waves may be variable. The disease is apt to be mild and uncomplicated in the beginning of a pandemic cycle. It increases in virulence to the peak of the wave and again decreases as the epidemic wanes.

<sup>74</sup> Brownlee. *Lancet*, Nov. 8, 1919.

<sup>75</sup> U. S. S. "Yacona" in 1919: 80 of 95 persons stricken within about one week.

FIG. 17.—CURVE OF THE INFLUENZA EPIDEMIC IN THE NAVAL TRAINING CAMP AT PELHAM PARK, NEW YORK, SEPTEMBER AND OCTOBER, 1918; SHOWING (1) CASES OF INFLUENZA, (2) CASES OF PNEUMONIA, AND (3) DEATHS. Note the steeple-like appearance of the curve, its symmetrical character, the short duration and explosive nature of the outbreak.

Although influenza spreads with amazing rapidity, it is not known to outstrip human travel. It moves from place to place in a pair of shoes. It sometimes seems to outrun travel; at least it is reported to break out simultaneously in widely separated parts of the globe. The vagaries of epidemics have given point to the name influenza, referring to some hidden influence.

No other disease is more *disabling* to community life, for the reason that so many are placed upon the non-effective list at the same time. Trade and travel become temporarily paralyzed; there is a shortage of doctors and nurses; hospital facilities are inadequate. The lesson of the past pandemic should teach us to mobilize the medical, nursing, hospital, and social service facilities in anticipation of such emergencies.

The *incubation period* is usually short—20 to 48 hours. The disease is presumably most communicable during the early stages. *Carriers* may spread the infection and are suspected. If the *Bacillus influenzae* is the cause of the disease, then bacillus carrying is exceedingly common. We do not know how long a person remains infective and little is known concerning carriers.

The question of *immunity* is not settled; it does not last a year. Second and third attacks were said to occur in 1889-90, but were uncommon in 1919. Some persons have recurring "influenza-like" attacks yearly.

During epidemics of influenza, other diseases do not prevail to the same extent. On the other hand, influenza is supposed to depress resistance so as to favor or hasten certain infections such as tuberculosis; of this, however, we lack proof. There seems to be an epidemiological relationship between influenza and cerebrospinal fever. The influenza bacillus is sometimes found in pure culture in meningitis, which may also occur as a complication of influenza. *Encephalitis lethargica* also bears an epidemiologic relation to epidemics of influenza.

Influenza was prevalent and fatal among horses in 1919, and the cause of much trouble to the army supply service. It also prevailed as an epizootic in this country in 1889-90. Other distempers among animals resemble influenza. The relationship to man is not known.

Crowding and human contact seem to favor its spread, although it travels with surprising rapidity through rural communities.

**Vaccines.**—Two classes of vaccines are used to protect against influenza: (1) influenza bacilli, (2) mixtures of pneumococci (Types I, II, III and IV), hemolytic streptococci, staphylococci aurei, influenza bacilli,<sup>76</sup> and other microorganisms.

Contradictory results have been reported with both types of vaccines. My own observations at Monson, Pelham Park Naval Training Station,

<sup>76</sup> Rosenow: *J. A. M. A.*, Jan. 14, 1919, Vol. LXXII, p. 31.

and elsewhere lead me to conclude that vaccines made with dead cultures of Pfeiffer's bacillus have no protective value whatever. Whether the polyvalent vaccines prevent pneumonic complications has not been established.

### ADMINISTRATIVE MEASURES

*Isolation* is possible, but not very practical during epidemics. In 1889-90 some large institutions were saved through a strict quarantine. Once within the walls, it is exceedingly difficult to control. In 1918-19, the infection was kept out of Goat Island in San Francisco Harbor, but finally got in. Several other localities had a similar experience. Australia established a quarantine which probably delayed the epidemic six months, when it was milder than elsewhere.

Patients for their own good should remain in bed during the febrile stage. This one measure would help control the spread of influenza as well as common colds. It is quite worth while to isolate the first case in a household in order to prevent a house epidemic. This may be done on lines precisely parallel to those described for diphtheria.

*Masks*.—During the 1919 outbreak, face masks were compulsory in San Francisco, Sacramento, and a few other cities. They did not lessen the incidence nor shorten the course of the epidemic.

*Closing* of schools, theaters, and other places of assembly, and regulations to prevent crowding were enforced in many cities during the epidemic of 1918-19, but so far as can be judged had no favorable effect whatever.

*Hospitalization* is not always advisable, for the condensation of many cases seems to favor the number and severity of complications. This same phenomenon is seen with measles. It is believed that pneumonic complications are sometimes contracted in large hospitals.

*Personal prophylaxis* follows the lines laid down for other infections transferred by the secretions from the mouth and nose. During epidemics individuals should avoid theaters, mass meetings, closed and crowded cars, and close contact with their fellow men, especially those who have catarrhal symptoms or fever. The danger from kissing, droplet infection, the use of the common drinking cup, the roller towel, handkerchiefs, pipes, toys, soda water glasses, spoons, and other objects recently mouthed should be emphasized; spitting ordinances enforced, ventilation and overcrowding of street cars corrected, and dust allayed. Hand to mouth infection should be remembered, and the hands washed before eating and the fingers kept away from the mouth and nostrils. Convalescence is often protracted, and subject to complications. Ample time should therefore be given to full return to health.

There may be unknown factors in the spread of influenza so that

our preventive measures lack precision and confidence. We have no specific prophylactic. So far as can be judged, the measures taken during the epidemic of 1918-19 did not control the disease to any appreciable degree.

## COMMON COLDS

(*Acute Coryza*)

More people probably suffer from common colds than from any other single ailment. Vital statistics give no hint of the prevalence and importance of these minor affections because the mortality is nil and the morbidity records are notoriously imperfect and difficult to collect. Could the sum total of suffering, inconveniences, sequelae, and economic loss resulting from common colds be obtained, it would at once promote these infections from the trivial into the rank of the serious diseases.

The common colds here considered are a group of acute infections of the mucous membranes of the nose, often extending into the throat; the larynx, trachea, or larger bronchi may be also involved. A common cold is not merely a congestion, it is an acute infectious disease.

Congestion and inflammation of the mucous membrane of the upper respiratory tract frequently occur as a result of irritants other than bacteria. Thus, chemical and mechanical irritants will produce a congestion or inflammation; an increased acidity causes a flaring up of the mucous membranes, especially of the nose; and many other local and reflex causes lead to acute or chronic catarrhal conditions of these membranes, which may become exquisitely sensitive and sometimes hypersusceptible. In the absence of the proper microorganism, however, these conditions do not develop into infectious colds, and are, therefore, not communicable.

The popular fallacy of colds being due to exposure to drafts, sudden changes of temperature, and chilling of the body clings persistently in both the professional and lay mind. These are predisposing causes and will not produce a cold without the presence of the specific cause. The bacteria usually found associated with these catarrhal infections are: staphylococci, streptococci (*viridens* and *hemolyticus*), pneumococci, influenza bacilli, the Gram negative cocci classed together as members of the *micrococcus catarrhalis* group, diphtheroid bacilli, and other microorganisms. The etiological relationship between these organisms and the disease is not always clear. Many of the above-mentioned bacteria are also found normally upon the mucous membranes of the nose, mouth, throat, and upper respiratory passages; auto-infections must, therefore, be common, and predisposing factors which diminish resistance have a special importance.

Tunnickliff<sup>77</sup> described a *Bacillus rhinitis* associated with acute and chronic rhinitis. Experimental inoculations of pure cultures produced colds.

Foster, working in my laboratory, has just confirmed and extended Kruse's<sup>78</sup> observations, showing the presence of a filterable virus in the secretions from the nose in common colds. This filtrate, as well as subcultures grown in selective media, when dropped into the nostril of healthy persons, produces a cold.<sup>78a</sup> There are different types of colds, due to different viruses, or to the associated bacteria. A number of negative results have also been recorded.<sup>79</sup>

Colds are contracted from other persons having colds, just as diphtheria is contracted from diphtheria. Arctic explorers exposed to all the conditions ordinarily supposed to produce colds do not suffer from these ailments until they return to civilization and become reinfected by contact with their fellowmen. A campaign to prevent the spread of the common cold would have much collateral good in aiding the suppression of tuberculosis and causing a diminution of pneumonia and other infections. Common colds occur in epidemics and have all the earmarks of a contagious disease. Colds are apt to go through all the members of a household, and outbreaks in schools, factories, and other places where people are closely associated, frequently occur and result in considerable loss of time and money.

While common colds are never fatal, the complications and sequelae are serious. These are: rheumatic fever, pneumonia, sinusitis, nephritis, and a depressed vitality which favors other infections and hastens the progress of organic diseases.

Common colds are perhaps most contagious during the early stages. If persons would isolate themselves by remaining in bed during the first three days of a cold, they would not only benefit themselves, but would largely prevent the spread of the infection. The contagiousness and severity of colds vary greatly in different epidemics and in different seasons of the year, depending upon the particular microorganism involved and other factors not well understood.

**Prevention.**—The prevention of colds consists, first, in avoiding the infection, and, secondly, in guarding against the predisposing causes. Contact should be avoided with persons who have colds, especially in street cars, offices, and other poorly ventilated spaces where the risk of persons coughing or sneezing directly in one's face is imminent. Contact with the infection may further be guarded against by a careful

<sup>77</sup> *Journ. Inf. Dis.*, 1913, XIII, 283.

<sup>78</sup> *Münch. med. Wochenschr.*, 1914, LXI, 1547.

<sup>78a</sup> *J. A. M. A.*, April 8, 1916, Vol. LXVI, No. 14.

<sup>79</sup> Park, W. H., Williams, A. W., and Krumwiede, C., *Jour. of Immunology*, Jan., 1921, Vol. VI, No. 1, p. 1., and others.

self-education in sanitary habits and cleanliness based upon the modern conception of contact infection.

Colds, like other diseases conveyed in the secretions from the nose and mouth, are often transferred by direct and indirect contact through lack of hygienic cleanliness and a disregard of sanitary habits. Kissing, the common drinking cup, the roller towel, pipes, toys, pencils, fingers, food, and other objects contaminated with the fresh secretions will transmit the disease.

The predisposing causes of colds include a number of conditions that depress vitality and thereby diminish resistance. The mechanism by which immunity is lessened is discussed on page 542. The principal predisposing factors in "catching" cold are: vitiated air, dust, drafts, sudden changes of temperature, exposure to cold and wet, overwork, loss of sleep or insufficient rest, improper food, and other conditions that lower the general vitality of the body. On the other hand, it must be clearly kept in mind that vigorous persons in prime health will contract a cold if they receive the infection.

Other important predisposing factors to colds are mechanical defects in breathing, or the filtering power of the upper respiratory passages, also local pathological conditions, such as adenoids, polypus, enlarged tonsils, deviation of the septum, chronic catarrhal conditions, all of which should receive appropriate treatment.

One of the most important predisposing factors to cold is breathing vitiated and dusty air. Good ventilation, therefore, with air not too dry nor too warm, and the allaying of dust would prevent many a cold. The bacteria accompanying colds are frequently found in the mouth, nose, throat and teeth of persons in good health. Cleanliness and care of these parts is, therefore, an important consideration in the prevention of the complications of common colds.

**Drafts and Chilling.**—Drafts in themselves cannot produce an infectious cold. The first symptom of the disease is a chill, which is not the cause, but the effect, of the infection. It is a common belief that the cold is caught when the chill occurs. The rigor frequently consists of only a transient chilliness, and it is during this time that the individual is sensitive to drafts which he thinks are producing his cold. See page 891.

A large number of investigators, including Lipardi,<sup>80</sup> Lode,<sup>81</sup> Pasteur,<sup>82</sup> Kline and Winternitz,<sup>83</sup> the New York State Commission on Ventilation,<sup>84</sup> Miller and Noble,<sup>85</sup> and others, have experienced variously

with animals and man, and all are in accord with the general conclusion that exposures to sudden changes of temperature lessen the resistance of animals to infection. Negative results are also found in the literature. It seems evident that the exposure of a portion of the body to cold is more likely to be followed by acute respiratory infections than when the entire body surface is subjected to the same low temperature, and the popular idea that drafts predispose to respiratory infections in some individuals is therefore not without foundation.

Chilling causes vasomotor contraction of the capillaries of the skin, which is doubtless designed to conserve body temperature; coincidentally there is turgidity of the erectile tissue of the mucous membrane of the turbinates, which is probably a defensive action. This congestion partly closes the nose and causes snuffling and increased secretion, which is ordinarily called a cold. A great variety of mechanical, chemical and even psychic stimuli will produce congestion of the cavernous tissue over the turbinate, in fact, the mucous membrane of the nose may become very sensitive, even hypersusceptible. Anaphylactic reactions to pollen and proteins are common manifestations of the nasal mucosa.

It has always been assumed that the contraction of the capillaries of the skin caused by chilling is attended with congestion of the internal organs, but Mudd and Grant<sup>86</sup> have shown that chilling of the skin causes vasomotor contraction and ischemia of the mucous membrane of the tonsils, palate, and pharynx, as well as the skin, with a drop in temperature and a subsequent increase in the bacteria on these parts. On rewarming the subject, the tonsils tend quickly to recover their blood supply, in some instances actually becoming hyperemic; the skin returns to about its normal condition, but the palate and pharynx remain somewhat ischemic. This may explain why chilling so often seems responsible for sore throat, which in this case would be an auto-infection.

Chilling has a great variety of effects. In some persons it causes diarrhea, in others neuralgic or muscular pain, sometimes it seems to be responsible for nephritis, bronchitis, pneumonia, etc. It brings out a latent malaria (page 290). Chilling is much less apt to cause harm if accompanied with active muscular exercise, which probably helps by keeping up the body temperature and vasomotor tone.

Drafts are much less apt to injure persons in good physical tone. They are, however, injurious to infants, the aged, and to susceptible individuals. Drafts are particularly apt to harm persons accustomed only to still, warm air. "It is not the engine drivers and firemen of trains that catch colds, but the passengers in the stuffy carriages." Coddling renders one susceptible to drafts, partly for the reason that the vasomotor impulses which contract the blood vessels of the skin are

<sup>86</sup> *Journ. Med. Research*, XL, 1, p. 53, May, 1919. *Jour. Exp. Med.*, 1920, XXXII, p. 87.

not sent out by the nervous mechanism, and consequently undue cooling of the part blown upon, and perhaps of the blood itself, takes place. Normally, when the wind blows upon the skin the vasomotor contraction reduces the supply of blood and the tendency to cooling is further met by a stimulus which increases heat production. While it is true that a draft can no more cause an infectious cold than it can cause diphtheria, nevertheless, it is true that a draft may increase the severity of a cold or be the predisposing cause by which immunity is lowered, thus favoring auto-infection. It is noteworthy that colds so contracted have little or no contagious tendency.

It is a mistake to think that the skin alone is involved in the question of drafts. The "hardening" of the skin as a prevention of colds is, therefore, a misnomer. The good effects of cold baths, exercise, fresh air, sunlight, and wholesome food do not consist in "hardening" the skin, but in improving the nutrition, stimulating the metabolism, helping the control of the nervous system, improving the tone of the vasomotor system, strengthening the musculature, and enriching the blood. In preventing the ill effects of drafts, therefore, the entire organization of the body must be considered, and not the skin alone.

### CEREBROSPINAL FEVER

Cerebrospinal fever is an infection with the meningococcus (*Diplococcus intracellularis meningitidis*, Weichselbaum). The essential lesions of the disease are chiefly focused upon the meninges of the brain and cord. The disease occurs both in localized epidemics and sporadically.

It is characterized by a clinical course of great irregularity, and before the use of specific serum had a very high case fatality rate. On account of the eruption which is often present, cerebrospinal fever was formerly called spotted fever, petechial fever, and malignant purpuric fever.

A clear distinction should be drawn between cerebrospinal fever and cerebrospinal meningitis: the former is caused by the meningococcus, the latter by a great variety of organisms, such as the tubercle bacillus, the pneumococcus, streptococcus, influenza bacillus, the colon bacillus, the typhoid bacillus, the bacillus of bubonic plague, and of glanders. The gonococcus may also cause meningitis as a secondary complication. The epidemic form, or cerebrospinal fever, is always due to the meningococcus.

The first epidemic outbreak of cerebrospinal fever was reported by Vieuxseux in Geneva in 1805. The next year James Jackson, Thomas Welch, and J. C. Warren investigated an outbreak in Massachusetts.

Since then numerous epidemics have occurred. In the New York epidemic of 1904-05 there were 6,755 cases and 3,455 deaths. This was part of a pandemic that started in Europe and within 5 or 6 years spread over the entire globe and then became quiescent, but was again stirred to renewed activity by the war.

Cerebrospinal meningitis is spread chiefly by carriers. The period of incubation is difficult to determine; it is stated to be from two to ten days, commonly seven. It may be one day in the young. It is extremely variable in some instances, as when carriers infect themselves.

**Epidemiology.**—Epidemics of cerebrospinal fever are usually localized, and rarely widespread. They almost always occur under crowded conditions, as in camps and on shipboard. Mining districts and sea-ports have suffered most severely. On the other hand, rural districts have also suffered severely, and widespread outbreaks have occurred in the tropics.

Cerebrospinal fever shows a distinct *seasonal prevalence* for the colder months of the fall and winter. In this respect it resembles other infections spread by the secretions of the mouth and nose, as pneumonia, scarlet fever, measles, diphtheria, etc. This is in sharp contrast to the seasonal prevalence of infantile paralysis which follows the curve of the summer diarrheas.

Children and young adults are most susceptible. Cerebrospinal fever is called a disease of children and soldiers. The soldiers who suffer most are those living in barracks, garrisons, towns and camps, rather than those on the march or in the field. The recruit and the young soldier are especially liable. Crowding, which favors contact infection, and fatigue which predisposes to this disease, explain the special liability under these conditions. Seasoned troops rarely suffer from the disease.

Predisposing factors play an important rôle in depressing immunity and facilitating infection with the meningococcus. Over-exertion, long marches in the heat, depressing mental and bodily surroundings, catarrhal inflammations, the misery and squalor of tenement life, and the sad conditions of some mining and laboring camps have long been recognized as predisposing causes. It is not the hardened soldier but the recruit in the making who is susceptible. The emergencies of the war again showed the hazard of haste in training the soldier and the sailor.

Weed has shown by experiments on animals that diminution of the pressure of the cerebrospinal fluid facilitates infection of the meninges with meningococci or any other microorganism that may be in the blood stream. The pressure of the cerebrospinal fluid may be decreased by puncture, by pressure on the vessels of the neck, and other ways. This may prove an important predisposing factor.

Cerebrospinal fever has long been recognized as a war disease. No

great epidemics of the disease occur among troops, but the affection prevails more or less in all armies. Sharp localized outbreaks occurred here and there. Between 1837 and 1850 a very widespread epidemic occurred in France, the disease being carried from place to place by the movements of the 18th Regiment of Infantry, in which the infection had established itself.

Cerebrospinal fever is not highly communicable, but spreads slowly and irregularly. It is usually difficult to trace connection between one case and the next—its movement shows curious pranks. This is now explained through carriers. Except in sharply localized outbreaks, it is rare to have more than one or two cases in a home, even where precautions are not taken. Sporadic cases are apt to crop out almost anywhere, at any time of the year. Only a small proportion of those who receive the infection develop the disease; the meningococcus is passed on from one to another until a susceptible individual is reached who develops meningitis.

The case fatality rate is usually high, about 75 per cent., occasionally being as low as 20 per cent. in some epidemics. The use of serum has reduced the death rate to about 25 per cent.

The immunity produced by one attack is not lasting. Councilman reports five instances in which the same individual is reported to have had the disease twice.

**Modes of Transmission.**—It is probable that the meningococcus enters the system through the mucous membrane of the nasopharynx. From this position it may reach the meninges directly through the lymph channels, but usually indirectly through the circulation. The experiments of Flexner in the monkey indicate that when the meningococcus is introduced into the cerebral cavity it escapes by a reversed lymphatic current, so that under these circumstances it may be found in the mucous membrane of the nasopharynx. Cerebrospinal fever is therefore spread through the discharges from the nose and mouth. It is a contact infection, due in the great majority of cases to rather direct association with cases or carriers. Indirect transfer is quite possible through fingers, dishes, pipes, handkerchiefs, toys, and other objects contaminated with fresh discharges. Droplet infection also plays its rôle. Crowding and close personal contact favor the spread of the infection. The meningococcus is so frail that our environment does not remain infective very long.

While carriers are chiefly responsible for the spread of cerebrospinal fever, it has recently been recognized that there are mild and abortive cases of the disease. These "missed" cases spread the virulent infection quite as actively as carriers. Cases of pharyngitis associated with and perhaps due to the meningococcus have been observed to occur frequently in endemic centers and in epidemic times. The theory of the

disease is that it is ordinarily mild and prevalent, and that only occasionally does it cause meningitis.

The meningococcus may pass through the cribriform plate of the ethmoid bone, but probably reaches the meninges in almost all instances by the blood stream. The disease is primarily a bacteremia.

The *meningococcus* is a strict parasite and is unknown in nature outside of the human host. It is a frail, Gram negative microorganism, resembling the gonococcus. Both are biscuit-shaped cocci; both grow feebly on artificial media. They are readily killed by drying, sunlight, heat, and other unfavorable conditions. They live a strict parasitic existence and cause diseases peculiar to man, with lesions which resemble each other, both as far as the character of the inflammation and the distribution of the cocci within the cells are concerned. As a rule, these two microorganisms are usually distinguished by the source from which they are obtained. Otherwise the differentiation depends upon their relation to the fermentation of sugars, agglutination, and complement fixation. The medium for the growth of the meningococcus must contain hemoglobin. Blood agar or liver agar is suitable. Involution, or "ghost" forms, appear in young cultures and after 24 hours autolysis is very active.

All bacteriologists now recognize the fact that there are very many different strains of meningococci, distinguished mainly by their reaction towards specific agglutinins. As many as 52 different strains were used to inject a horse for the purpose of preparing a polyvalent serum. Gordon recognized 4 groups; French observers<sup>87</sup> speak of meningococci and parameningococci, the latter being commonly associated with the disease in the United States. A classification around definite types, as in the case of pneumococci, has been attempted, but is not yet definite. The Hygienic Laboratory of the United States Public Health Service recognizes 12 strains, which comprise 4 agglutinating and 5 tropin groups, including all known types.

The meningococcus has been found in the blood almost constantly in the early stages of the disease. The modern notion of cerebrospinal fever is that it is primarily a septicemia with a predilection to localize in the meninges. Other structures are often attacked, especially the joints and the heart valves. In fulminating cases the septicemia may overshadow the meningitis. Death may occur in 24 hours, or less.

The effect of sunlight on the meningococcus is rather surprising, the organism being very resistant to it. Elser and Huntoon<sup>88</sup> found that some strains survived eight or nine hours' exposure; Foster and Gaskell,<sup>89</sup> seven hours' exposure. All strains tested survived one or two

<sup>87</sup> Dopter: *Compt. Rend. Soc. de Biol.*, 1909, 67, p. 74.

<sup>88</sup> *Journ. Med. Research*, XX, 1909, p. 494.

<sup>89</sup> *Cerebrospinal Fever*. Cambridge Univ. Press, 1916.

hours' exposure to full sunlight. Drying, on the other hand, has a marked effect in killing meningococci. No growth could be obtained from cover slips with meningococcus cultures after five or ten minutes' drying in a sulphuric acid desiccator. When dried on glass in ordinary air, twenty-four hours' exposure has been found by various observers to destroy the organism. Elser and Huntoon found that under certain circumstances the meningococci can survive somewhat longer. It is very sensitive to germicides and heat.

**Carriers.**—Healthy passive carriers outnumber the cases of cerebrospinal fever 10 or 30 to 1. Persons directly associated with the patient rarely take the disease, but often become carriers and thus transmit the infection to others, and these to others and so on indefinitely. Only a small percentage of carriers is susceptible and develops the disease. Cerebrospinal fever is disseminated almost wholly by carriers.

The meningococcus is found quite constantly in the nasopharynx during the first five days of the disease. It then begins to disappear and is gone after four weeks or a few months of convalescence. Only rarely are chronic active carriers found. On the other hand, a large proportion of the healthy persons who come in immediate contact with a case or a carrier become carriers. The healthy passive carrier therefore is the chief factor in disseminating the infection.

The number of carriers varies with circumstances. In Boston in 1917, we found from 1 per cent. among persons who had no known contact with the disease, up to 80 per cent. among intimate contacts under military conditions. On account of the carrier state in this infection, Gordon considers all persons who have come within 3 yards of a case under conditions favorable for infection as "contacts."

A mother who nurses a meningococcic infant is sure to become a carrier, and vice versa. Of 16 room-mates of a soldier stricken with meningitis, 10 were carriers. The meningococcus has been found in as many as 100 per cent. of those in the immediate entourage of a case. It was a common experience during the World War to find 20, 30 and 40 per cent. of a command, in the army or navy, to be carriers. The percentage increases with the degree of crowding and the intimacy of contact. Where people eat, sleep, work, and wash together as in camps and on shipboard, there is every facility for interchange of the flora of the mouth and nose.

The number of carriers varies with factors other than crowding. There are more in the cold months than in summer, more when an epidemic is fully developed than during the waxing and waning stages, and more in severe epidemics than in mild.

Most carriers are temporary, at least, the meningococci cannot be found after a month or two. Hundreds of carriers observed in Boston

during the World War cleared up promptly with the coming of warm weather. This is a common experience.

Almost pure cultures of meningococci are obtained from the nasopharynx of many carriers; in others only an occasional colony. All intermediate grades occur. Only a very small percentage of the carriers develops the disease. This may be due to an immunity or to lack of facilitating factors which determine infection of the meninges. Most carriers are adults, whereas the disease has a special predilection for children. Differences in the anatomical structure of the lymphatic structure may account for the resistance of adults. The quantity of carriers does not seem to influence the incidence of the disease. During the World War the number of carriers discovered was so great that it became impractical from a military standpoint to isolate them. In some places separate training camps for meningitis carriers were established.

There is no evidence that chronic carriers develop the disease. I cannot escape the conviction that many of the carriers of meningococci are not dangerous, either to themselves or their fellow men. This may be on account of the lack of virulence of the organism. Perhaps we have a similar situation with meningococcus carriers that we have in diphtheria carriers, but we have no method at present of distinguishing true or virulent carriers of cerebrospinal fever from the harmless varieties.<sup>90</sup>

Many measures have been tried to cure carriers. Local applications of germicidal substances such as chloramin in 0.5 to 1.0 solutions (Gordon), peroxid of hydrogen, various cresol preparations, permanganate of potash, and zinc sulphate have been tried. The difficulty is in reaching the meningococci. Warm, moist rooms, with and without germicides added to the air, have been tried. Vaccines do not relieve carriers. Those with tonsillitis and catarrhal inflammation of the nasopharynx lose the meningococcus more slowly than those with normal mucous membranes. No measures so far are effective.

*The Recognition of Meningococcus Carriers.*—The specimen should be taken from the roof of the nasopharynx, with a sterile cotton swab, guarded by a glass tube, as shown in the illustration (Fig. 18). It is important to prevent contaminations by organisms in the mouth and saliva.

Proper technic in obtaining the specimen and in seeding the plates can only be gained by practice.

The meningococcus is very frail, and therefore the plates should be made immediately. It is very sensitive to acid and is soon destroyed by the acidity of contaminating organisms. Sodium chlorid is also toxic to the meningococcus, and therefore salt solution should not be used as a diluent, and salt is commonly omitted from the culture media.

<sup>90</sup> Ponder, *Brit. Med. Journ.*, Sept. 18, 1920, p. 427.

The meningococcus may be grown upon sheep-serum dextrose agar, ascitic agar, blood-serum agar, pea-extract trypsin agar, or liver agar.

The sheep-serum agar is made with one part of sheep serum and three parts of double distilled water. The sheep serum is obtained by clotting and centrifuging. This diluted serum is then sterilized fractionally in the Arnold for thirty minutes on three successive days. The agar is prepared separately with 2 per cent. agar and 1 per cent. peptone,

FIG. 18.—WEST SWAB TUBE.

reaction 0.2 to phenolphthalein. The plates are made by adding 1 c. c. of the diluted sheep serum to 5 c. c. of the liquefied agar at 40° C.

The Petri plate is seeded with the swab by simply touching the tip to one place on the plate. From this spot the material is spread by means of a loop or flat wire. The plate is then incubated over night, at 37° C. Watch for small moist colonies with regular outline; then let the plates stand at room temperature (about 25° C.) for several hours. This per-

FIG. 19.—DIAGRAM ILLUSTRATING THE METHOD OF TAKING MATERIAL FROM THE NASOPHARYNX BY MEANS OF A SPECIAL SWAB. W—wire holder of S—swab; P—soft palate; D—tongue depressor. (After Dopter.)

mits the colonies of *Micrococcus catarrhalis* to grow and affords a ready method of differentiation, for the meningococcus does not multiply at room temperature.

Young meningococcus colonies are colorless, translucent, have a regular contour (lens effect), uniform granular structure, mix easily in salt solution, and make an homogeneous suspension. Suspicious colonies may be tested directly by the drop method on a microscopic slide, fished to sheep-serum dextrose agar slants or other suitable media, incubated over night, and tested for macroscopic agglutination. The cultures for the

agglutination test should be less than twenty-four hours old, for by that time involution forms appear, and the older colonies make less satisfactory suspensions.

The agglutination is best done macroscopically at 56° C. and the tubes are allowed to stand at this temperature for 12 to 20 hours before taking the final reading.

Cultures that are agglutinated with a dilution of 1:100 with a polyvalent serum, but that fail to agglutinate in normal control serum in half this titer, may be regarded as presumptively positive. After the presumptive test, careful study of the culture must be made in order to identify it.

The meningococcus must be carefully distinguished from *Micrococcus flavus*, *Micrococcus crassus*, *Micrococcus pharyngis siccus*, *Micrococcus catarrhalis*, and other confusing organisms. For details see Olitsky's method<sup>91</sup> and Krumwiede's macroscopic slide agglutination test.<sup>92</sup>

**Prevention.**—A better knowledge of the facts concerning cerebrospinal fever has shaken our confidence in the practical value of preventive measures. Theoretically the case is plain; practically, very difficult. The wide prevalence of the infection, the large number of carriers, the existence of mild and abortive cases, all add to the complexity of the administrative control of the disease. It is not clear that any of the measures so far taken have either materially influenced the course of epidemics or prevented the spread of the disease.

The first problem is the recognition of cases and strict isolation with a view of diminishing the number of carriers. Cerebrospinal fever is a disease which requires skilled laboratory facilities, and these should be provided by health authorities in all communities.

Individual prophylaxis consists in guarding against the well known predisposing causes such as over-exertion, fatigue, exposure, depressing influences of all kinds, and catarrhal inflammation of the nasopharynx. Coryzas and catarrhas should receive attention, because they are not only facilitating factors of infection, but are sometimes associated with meningococci. Crowding must be avoided. Sprays and douches have no protective value, and injudiciously used may be mischievous. They should be used only under skilled medical advice. Sanitary habits of the sort that discourage the carrying of infection to the mouth and nose should be taught and learned. General health and the tone of the machine should be maintained.

In military practice, the isolation of meningitis carriers is not only extravagant and against military efficiency, but also impractical and non-effective. The search for carriers and their care should not cause neglect of the more general measures, such as prevention of crowding,

<sup>91</sup> *J. A. M. A.*, LXX, 3, Jan. 19, 1918, p. 153.

<sup>92</sup> *Ibid.*, LXIX, 1917, P. 359.

control of hand to mouth infection, the allowance of ample time for the "hardening and seasoning" of recruits, protection from weather, overwork, and fatigue, and the use of all measures that will promote the general health of the command.

We must frankly admit that when cerebrospinal meningitis has once become epidemic it cannot be stamped out by any known means of practical application.

This does not mean that we should assume a supine attitude, for, even though the disease cannot be satisfactorily controlled, a certain number of secondary cases can be prevented. Vaccines have been tried, but their usefulness has not been established. The procedure is logical and deserves extended observation. Agglutinins develop in the blood of those vaccinated.

Antimeningitis serum is useful in the treatment of the disease; it is not practical as a preventive. It must be introduced into the subdural space by lumbar puncture. Intravenous injections to counteract blood infection are also indicated. The serum should always be matched with the particular strain of meningococcus to obtain specific results. The serum should be provided free of cost or at a minimum price by health authorities. Further, boards of health should provide laboratory facilities for the bacteriological diagnosis of the disease, and the recognition of carriers.

## CHAPTER IV

### INSECT-BORNE DISEASES

#### GENERAL CONSIDERATIONS

The fact that disease may be transmitted through the bites of insects was suspected for years, but it was not until 1893 that it was demonstrated as a new principle by Theobald Smith in the case of Texas fever of cattle and the tick.<sup>1</sup> Since then many diseases have been added to the list, which is constantly growing. We now know that some diseases are always transmitted through insects and others occasionally. A thorough comprehension of the subject is necessary for sanitarians and others in the fight against disease in all climates and in all countries.

It may be stated as a general law that, if a period of incubation in the insect is necessary, it indicates that the parasite probably belongs to the animal kingdom and passes part of its life cycle within the insect. This constitutes the so-called *extrinsic period of incubation*. Malaria and yellow fever are examples of this class, which is spoken of as *biological* transmission. If, on the other hand, insects convey infection at once without a period of incubation in the insect, the transfer is a *mechanical* one; in this case the insect does not play the part of an intermediate host in the true biological sense, and there is no cycle of development of the parasite within the insect. These cases are almost all bacterial infections.

It may be stated as a general rule that the insect hosts are not harmed by the parasites which they harbor and which are pathogenic for man. Thus, the malarial protozoön is pathogenic for man, but apparently harmless for the mosquito. The same is true of yellow fever and the *Stegomyia*, Texas fever and the tick, plague and the flea, sleeping sickness and the tsetse fly, typhoid and the house fly, typhus fever and the louse, etc.

The *intermediate* host in the zoölogical sense is that animal which harbors the asexual phase of the life cycle of the parasite; the *definitive* host is the animal which harbors the sexual phase. Thus, in malaria man

<sup>1</sup> The other names associated with the early work upon insects and their relation to disease are: Manson, Finlay, Ross, Grassi, and the U. S. Army Commission—Reed, Carroll, Lazear, and Agramonte.

is the intermediate host, the mosquito the definitive host. In popular parlance, the insects are spoken of as the intermediate hosts in all cases.

Insects transfer infections mechanically in a variety of ways. The mouth parts, legs, or outer surfaces of the body may be smeared with the virus, which is then simply carried to the lips, fingers or food, and thus enters the susceptible individual; or the virus may remain attached to the proboscis of a biting insect, thus transferring the infection very much as a hypodermic needle would; or the virus may be contained in the dejecta of the insect and be scratched or rubbed into the wound made by the bite; or the virus may be contained in the digestive tube or the body cavity and be released when the insect bites or is crushed.

Insect-borne infections are types of true endemic diseases, and they are necessarily limited in geographical distribution to the habitat of the insect host. They prevail especially in tropical and warm, moist regions, where insect life abounds. The seasonal prevalence of insect-borne diseases is therefore distinctive.

As a rule, only one species, or at most a single genus, acts the part of a host for any particular infection, excepting in the mechanical transference of infection by insects. Malaria is confined to *Anopheles*, yellow fever to *Stegomyia*, Texas fever to the *Margaropus annulatus*, sleeping sickness to the *Glossina palpalis*, etc. This is a question of specificity. The specific nature of some of these diseases may be due to the fact that the parasite is not pathogenic for other hosts. Thus, most of the insect-borne diseases do not occur naturally in the lower animals and cannot as a rule be transferred even though large amounts of the infected blood be inoculated. The disease may be specific, in the sense that it is confined to one species, because the insect conveying the infection refuses to bite other than its own host. True specificity is found in all the cases of biological transference, whereas mechanical transference of infection may take place through widely separated genera.

In some instances the virus is transmitted "hereditarily" through the insect from one molt to another, and even from one generation to the next. So far as known, however, hereditary transmission takes place only in those "insects" having an incomplete metamorphosis, such as the ticks. Brues suggests that the hereditary transmission of a virus is practically impossible in insects passing through complete metamorphosis, owing to the active phagocytosis during the pupal stage.

Protozoa, bacteria, and even parasitic worms may be transferred by insects. The character of the disease cannot be predicated from the nature of the insect host. Thus, ticks convey *Piroplasma* and also spirochetes; flies convey trypanosomes, bacteria, the eggs of worms, and a variety of other infections; mosquitoes are concerned in the transmission of the plasmodium (a protozoön, filaria (a round worm), and spirochetes (a filtrable virus).

Insect-borne diseases may occur in great epidemics, as yellow fever, malaria, dengue, typhus, relapsing fever, etc. When this occurs it means that the particular insect involved prevails in enormous numbers in the epidemic area.

Ticks and mites belong to the lower class of the Arachnida and are not, strictly speaking, insects (insecta), but are here considered in the same group for practical convenience.

All the parasitic animals which live upon man and other animals may act as go-betweens in the transportation of the microörganisms of disease. Parasites which live upon the skin are known as *ectoparasites*, in contradistinction to *endoparasites*, which live within the body. The ectoparasites may be temporary parasites, as the mosquito; or permanent, as the tick, which spends all but its earliest and last days attached to the skin of its host. Between these extremes there are parasites spending more or less of their life attached to the host; thus, the bedbug and flea are temporary, whereas lice are more permanent parasites.

FIG. 20.—A SOUTH AFRICAN BLOOD-SUCKING FLY (*Pangonia*), ILLUSTRATING LONG PROBOSCIS TO PIERCE HEAVY FUR OF CERTAIN ANIMALS. (Brues.)

Many of the insect-borne diseases were formerly known as "place diseases." Thus, in yellow fever it was realized that the infection was not conveyed directly from man to man, but it was believed that the house or place became infected, and it was thought that the virus lived in the soil, upon the bedding, or on the clothing. This led to the notion that *fomites* or inanimate objects played an important rôle in the transference of disease. The early studies in bacteriology gave countenance to this view until our knowledge of the part played by insects and the importance of "contacts" and "carriers" has placed fomites in a subordinate and oftentimes negligible position in public health work.

The prevention of the insect-borne diseases depends upon a knowledge and thorough comprehension of three factors: (1) the disease, (2) the parasite, and (3) the insect. The suppression or control of the insect depends upon a precise knowledge of its biology. Entomology, therefore, has become a vitally important subject so far as preventive medicine is concerned. Without an acquaintance of the life history and habits of

the insect host there will be economic loss, wasted energy, and disappointing results. The malarial mosquito is active at night and breeds in the swamps; the yellow fever mosquito is active by day and breeds about houses. Other mosquitoes have their own particular breeding and hiding places. The suppression of lice depends largely upon bodily cleanliness, the suppression of the bedbug upon house cleanliness, the dangerous fleas come largely from association with other animals, the flies from manure and decomposing organic filth, the ticks from other animals and from the infested ground and woods.

For the control of the insect-borne diseases it is not always necessary to exterminate the particular insect host. In fact, the extermination of a particular species, much more a genus, is practically a biologic impossibility. A material reduction in the numbers of the insects in a particular area will often result in an elimination of the disease.

The geographical distribution of the disease is always more limited than the geographic distribution of the insect host: *Anopheles* exist in many places where there is little or no malaria. *Stegomyia* mosquitoes are numerous in the Philippines, but yellow fever has not yet been carried there.

In the migration of insect-borne diseases it is usually the human host and not the insect that acts as the traveler. Insects, as a rule, do not go great distances of their own volition, and never overseas or from one country to another, unless taken in the conveyances of man or upon some animal host. When yellow fever or malaria go from one country to another, the infection is translated in man. The infected mosquitoes are rarely transported, except occasionally upon wooden sailing vessels with water barrels that afford breeding places.

An apparent exception to this statement is the case of plague. It is the rat rather than man that spreads plague from land to land. In this case, however, the disease is primarily an infection of the rat, which carries the flea along and man is secondarily attacked. Flies, mosquitoes, and other insects are known to travel or be blown a mile or more upon the wing.

An effective campaign against mosquitoes, flies, or other insect pests requires the expenditure of time and money. Further, it requires the assistance of the entomologist, the engineer, and the practical administrator. When the campaign involves extensive drainage or filling-in operations, this calls for the services of an engineer who has specialized along these lines. To attack the problem without a complete knowledge obtained from a careful study of the habits and breeding places of the particular species of insect will probably result in economic waste. The habits and habitat of some species may vary in different localities, and a careful study of the local conditions is important to insure success. In the organization of a mosquito campaign the several branches of the work

may be allotted to special divisions, each consisting of a foreman and crew. These men become skilled in their particular duties, and efficiency is thereby greatly promoted. One division should have charge of the oiling, another of the fumigation, another should seek to destroy the natural breeding places, another should attend to the screening, etc. In fly suppression one division should look after the storing and handling of horse manure, another to garbage and organic refuse, and so on. All the work must be centralized under the direction of one person with executive ability and a thorough understanding of the problem.

The suppression of insects and household vermin is essentially a question of cleanliness. The most effective measures are those which strike at the breeding places, and these will be considered separately under mosquitoes, flies, ticks, lice, fleas and bedbugs. Next to the suppression of their breeding places, the most important measure in a household is to starve out these pests. Food must be so protected that insects, mice, and rats cannot gain access to it. Floors and other surfaces must be kept clean, so that they do not have the least film of organic dirt upon which insects feed. There should be no cracks or crevices to collect dust and dirt, which offer comfort for insect life. Cleanliness and incessant care must not only be exercised in the household itself, particularly in kitchen, pantry, dining room, cellar, attic, and toilets, but must also include the back yard and surroundings of the house. Old cans and broken bottles, rubbish, garbage, and general untidiness around the household afford breeding places, hiding places, or food for vermin.

All the blood-sucking parasites must be regarded as dangerous. If they do not play the rôle of an intermediate host in the biological sense, they may occasionally transfer infections in a mechanical way, or the little wounds may allow the entrance of such infections as erysipelas, the pus cocci, anthrax, tetanus, and other microorganisms. Further, all blood-sucking parasites are potentially dangerous, in that new diseases may be established as the old ones must have been established at one time through the triple alliance of host, insect, and parasite.

Insect-borne diseases may be controlled by attacking the insect, or the parasite in the host, or both. The object should be to attack the weakest link in the chain.

Science has demonstrated the danger from insects. Experience long ago decided that a healthy home must be free of insects and vermin of all kinds—it remains for the future to extend this kind of cleanliness to municipal housekeeping and rural sanitation.

The principal insect-borne diseases, their causes, and the insect responsible in each case are stated in the following table:

## The Principal Insect-borne Diseases

DISEASE	CAUSE	INSECT
MOSQUITOES		
MALARIA (Laveran, 1880, the parasite; Ronald Ross, 1895-1898, relation to the mosquito)	<i>Plasmodium malariae</i> (Laveran) <i>Plasmodium vivax</i> (Grassi and Feletti) <i>Plasmodium falciparum</i> (Welch)	<i>Anophelinae</i>
YELLOW FEVER (Reed, Carroll, Lascar, and Agramonte, 1903-1902)	A filtrable virus <i>Leptospira icteroides</i> (Noguchi, 1919)	<i>Stegomyia calopus</i>
FILARIASIS (Demarquay, 1863; Manson, 1899)	<i>Filaria bancrofti</i>	<i>Culex fatigans</i>
DENGUE (Graham, 1903; Ashburn and Clegg, 1907)	A filtrable virus (?)	<i>Stegomyia calopus</i>

## FLIES

SLEEPING SICKNESS (Gambian) (Dutton, 1902)	<i>Trypanosoma gambiense</i>	<i>Glossina palpalis</i> —A tsetse fly
SLEEPING SICKNESS (Rhodesian) (Stephens & Fantham, 1910)	<i>Trypanosoma rhodesiense</i>	<i>Glossina morsitans</i> —A tsetse fly
TYPHOID, CHOLERA, DYSENTERY, etc. Contagious ophthalmia, "pink eye," erysipelas, anthrax, glanders, skin infections. Small-pox and other exanthemata.		Flies and other insects, by mechanical transmission
NAGANA (of cattle, etc.) (Bruce, 1895)	<i>Trypanosoma brucei</i>	<i>Glossina morsitans</i> —A tsetse fly
SURRA (of horses, etc.) (Steel, 1885)	<i>Trypanosoma evansi</i>	<i>Tabaninae</i> , <i>Stomoxys calcitrans</i> , and other biting flies; also fleas
PAPPATACI FEVER (3 day fever) (Doerr, 1909)	A filtrable virus (?)	<i>Phlebotomus poppalatii</i> —A dipterous biting gnat
CALABAR SWELLING (Loa loa) (Cobbold, 1864; Manson, 1891)	<i>Filaria diurna</i>	<i>Chrysops dimidiatus</i> —A biting fly
SOUTH AMERICAN TRYPANOSOMIASIS (Barbiero fever) (Chagas, 1909)	<i>Trypanosoma cruzi</i>	<i>Lamprophya megistus</i> —A hemipterous biting insect
DEER-FLY FEVER (Francis, 1919)	<i>Bacterium tularensis</i> (McCoy and Chapin, 1912)	Biting fly ( <i>Crysops</i> )

## TICKS

TEXAS FEVER (of cattle) (Smith & Kilbourne, 1893)	<i>Babesia bigemina</i>	<i>Margaropus annulatus</i>
ROCKY MOUNTAIN SPOTTED FEVER (Ricketts, 1906; Wolbach, 1916)	<i>Rickettsia</i>	<i>Dermacentor andersoni</i>
RELAPSING FEVER (W. Africa) (African tick fever) (Dutton and Todd, 1904)	<i>Spirochaudinnia duttoni</i>	<i>Ornithodoros moubata</i> ; also lice, and perhaps bedbugs, etc.

## BEDBUGS

EUROPEAN RELAPSING FEVER (Obermeier, 1873)	<i>Spirochaudinnia recurrentis</i>	<i>Clinocoris lectularis</i> (?) <i>Pediculi</i> (?)
INDIAN KALA-AZAR (Ross, 1903)	<i>Leishmania donovani</i>	<i>Clinocoris rotundatus</i> <i>Conorhinus</i> (?)

(Continued on next page.)

## Insect-borne Diseases—(Continued)

DISEASE	CAUSE	INSECT
LICE		
ALGERIAN RELAPSING FEVER (Sergeant and Foley, 1910)	<i>Spiroschaudinnia berbera</i>	<i>Pediculi</i>
EUROPEAN RELAPSING FEVER (Obermeier, 1873)	<i>Spiroschaudinnia recurrentis</i>	<i>Clinocoris</i> (?) <i>Pediculi</i> (?)
ASIATIC RELAPSING FEVER (Carter, 1877)	<i>Spiroschaudinnia carteri</i>	<i>Pediculus vestimentis</i> (?)
TYPHUS FEVER (Nicolle, 1909; Ricketts & Wilder, 1910; Anderson & Goldberger, 1910)	<i>Rickettsia prowazeki</i>	<i>Pediculus vestimenti (corporis)</i> <i>Pediculus capitis</i> <i>Pediculus humanus</i>
TRENCH FEVER	<i>Rickettsia pediculi</i>	<i>Pediculus humanus, var. corporis</i>
FLEAS		
PLAGUE (Kitasato, 1894; Yersin, 1894)	<i>Bacillus pestis</i>	<i>Xenopsylla cheopis</i> and others
INFANTILE KALA-AZAR (Pianese, 1905)	<i>Leishmania infantum</i>	<i>Ctenocephalus canis</i> (?)

The following table gives a list of the principal diseases which are transmitted by "intermediate" hosts other than insects.

DISEASE AND ADULT PARASITE	INTERMEDIATE OR USUAL HOST	INFECTING STAGE OF PARASITE	MODE OF INFECTION
Liver fluke <i>Fasciola hepatica</i>	Snails <i>Limnaeus</i>	<i>Cercariae</i>	Ingestion
Liver fluke <i>Clonorchis endemicus</i>	Fish	Encysted stage	Ingestion
Lung fluke <i>Paragonimus westermanii</i>	Fresh-water crab <i>Potamon dehaanii</i>	Encysted larvae	Ingestion
"Katayama disease" <i>Schistosomum japonicum</i>	Fresh-water snails <i>Katayama nosophora</i>	<i>Cercariae</i>	Through the skin
Fish tapeworm <i>Dibothricephalus latus</i>	Pike, salmon, etc.	<i>Plerocercoids</i>	Ingestion
Dog tapeworm <i>Dypilidium caninum</i>	Dog fleas and dog lice	<i>Cysticercoids</i>	Contact with dogs
Rat tapeworm <i>Hymenolepis diminuta</i>	Meal moth, <i>Asopia farinalis</i> and other insects	<i>Cysticercus</i>	Ingestion
Dwarf tapeworm <i>Hymenolepis nana</i>	(?)	<i>Cysticercoid</i>	Ingestion
Pork tapeworm <i>Taenia solium</i>	Swine	<i>Cysticercus</i>	Ingestion
Beef tapeworm <i>Taenia saginata</i>	Cattle	<i>Cysticercus</i>	Ingestion
Hydatid disease <i>Echinococcus granulosus</i>	Dogs	<i>Onchosphere</i>	Ingestion
Guinea worm <i>Dracunculus medinensis</i>	A small crustacean <i>Cyclops coronatus</i>	<i>Larvae</i>	Ingestion
<i>Lamblia intestinalis</i>	Rats, mice	Encysted stage	Ingestion
<i>Trichinosis</i> <i>Trichinella spiralis</i>	Swine	Encysted stage	Ingestion
Infectious Jaundice, Weil's Disease <i>Spirochaeta icterohaemorrhagiae</i>	Rats*		

\* Other diseases transmitted by rats, see page 335.

**INSECTICIDES <sup>2</sup>**

Practically all germicidal agents are also insecticides. There are some exceptions to this statement, notably formaldehyd, which is a potent germicide, but has little or no effect upon insect life in its gaseous state.

The action of insecticides may be considered under three classes: (1) those that act as general protoplasmic poisons, such as strong acids or alkalies, hydrocyanic acid, sulphur dioxid, etc.; (2) those that suffocate the insects, such as oily substances; (3) those that act upon the nervous structures, such as chloroform, ether, and other general anesthetics.

Another classification considers insecticides under four groups: (1) those used by contact in liquid form or in solution; (2) those used by contact in dry or powdered form; (3) those used by contact in vapor form; (4) those used by mixing with food and which are poisonous when ingested.

Insects differ markedly in their power of resisting insecticides. Those with well-developed chitinous protection, such as bedbugs and roaches, are more difficult to kill than flies, fleas, and mosquitoes. Many insecticides have marked specific action. Thus, iodoform kills lice within 10 to 15 minutes, but has practically no harmful action on bedbugs, and very little effect on fleas. Pyrethrum has a more powerful action on bedbugs than on lice, etc.

The most practical of the insecticides for the destruction of the winged insects in an enclosed space are those that may be used in the gaseous state. Of these, sulphur dioxid, and hydrocyanic acid gas are most commonly employed and are most reliable. The method of killing insects by gases and fumes is called fumigation. See pages 1352 and 1390.

**Preparation of the Room for Fumigation.**—It is more important to seal tightly a room in which insects are to be destroyed than where only a germicidal action of the gas is looked for. Insects may escape through minute openings, and they may hide in nooks and cracks where the gas permeates slowly and feebly, or may take cover under the folds of crumpled paper or folded fabrics, and thus escape the insecticidal action of the gas. Self-preservation tempts mosquitoes and other insects, as well as rats and mice, to seek the light when in the presence of an irritating gas. It is, therefore, convenient to darken the place to be treated, leaving one source of light. The dead vermin may then be readily collected about this place.

<sup>2</sup>All insecticides sold in interstate traffic in the United States must comply with the Insecticide and Fungicide Act of 1910, administered by the U. S. Dept. of Agriculture.

Strips of paper should be pasted over doors and windows. Cracks and crevices may be caulked with towels, waste, or other suitable substance. Ventilators, fireplaces, hot-air registers, and all openings into the room must be covered, otherwise both the gas and the insects will escape. Closets and small doors should be opened and all drawers, lockers, and similar places exposed in such a way that the gas may have fresh access to remote corners. Furniture should be moved away

FIG. 21.—EXAMPLE OF SEALING DOORS FOR PURPOSE OF FUMIGATION.

from the walls. Fabrics, paintings, instruments, bright metal work, or other objects liable to injury may be removed or covered, especially when sulphur is used. See also page 1390.

**The Relative Efficiency of Insecticides.**—McClintock, Hamilton, and Lowe<sup>3</sup> tested a number of insecticidal substances, the values of which are shown in Table 4, which gives a list of the substances tested and the species of insects used in the experiments, together with the quantity of each substance which, when properly transformed into vapors, was

<sup>3</sup> *Jour. Am. Pub. Health Assn.*, Vol. II, No. 4, Apr., 1911, p. 227.

sufficient to kill the species indicated. The coefficient column shows the inverse ratio between this quantity and 8 grams, the weight of sulphur which, when burned, kills the bedbug in 800,000 c. c. of inclosed space. The efficient dilution of the vapors of any substances may be obtained from this coefficient by multiplying by 100,000.

For example, if one wishes to use carbon disulphid, by consulting No. 28 in the table it is shown that 24 grams were required to kill bedbugs, while only 8 grams of sulphur were required. It is therefore only one-third as strong and its coefficient is 0.3+. Its efficient dilution is 33,000.

Table 4.—INSECTICIDES

Time of exposure—Varied as conditions required.  
Column 1—Quantity used to kill the specified insect.  
Column 2—Coefficient of efficiency compared with the efficiency of sulphur dioxide on bedbugs.

Substance	Bedbug		Cockroach		House Fly		Clothes Moth		Mosquito	
	1	2	1	2	1	2	1	2	1	2

32* Nicotin, 80% Sol.	25	4	25	4	6	20	25	40	1	100
33 Hydrocyanic Acid, as Potassium Cyanid	6.3	1.3	6.3	1.3	2	4	1	8	2	40
34 Paraform	8+	1	8+	1	4	2	8	1	1	8
35† Formaldehyd 40% Sol.	54+	0.1	54+	0.1	16+	0.5	16+	0.5	8+	1
36 Stramonium Leaves	10	0.8	10	0.8	10+	0.8	10+	0.8	4	2
37 Sabadilla Seeds	8+	1	8+	1	16	0.5	16+	0.5	4	2
38 Chrysanthemum Flowers	80+	0.1	80+	0.1	2.6	3	4	2	1	8

The + sign after a number indicates that this quantity was the largest used and that it was insufficient.

\* Coefficient of nicotin based on 100% alkaloid.

† Quantity of formaldehyd to be an efficient germicide is 13½ c. c. or a coefficient of 0.625.

The best methods of generating gases for fumigating purposes are considered below. For further information concerning these substances, with special reference to their germicidal action, see Section XIV.

To insure success the gas used to fumigate a room should be liberated in a large volume in a short time. If the gas is evolved slowly much of it will be lost before the room can become charged with a sufficient amount to kill the insects.

The amount of gas and the time of exposure stated in each case are the minimum. When large, leaky, or irregularly shaped spaces are to be fumigated, the amount of gas should be increased and the time of exposure prolonged. It is also advisable to generate the fumes in as many different places as practicable, as this favors rapid diffusion.

**Sulphur.**—Sulphur is one of the most valuable insecticides we possess. It may be used either as a gas— $\text{SO}_2$ —or in its powdered form—flowers of sulphur.

*Sulphur dioxid* is destructive to all forms of life. It will kill mosquitoes, flies, fleas, roaches, bedbugs, and all kinds of vermin,<sup>4</sup> including rats and mice. While sulphur dioxid is one of the most dependable insecticides it is a rather feeble germicide. It diffuses poorly and has feeble penetrating power, requires expensive or cumbersome apparatus, and much labor. It is also rather slow and has some risk of fire. It is further limited in practice on account of its destructive and corrosive action due to sulphurous acid and sulphuric acid produced in the presence of moisture. Fortunately the dry gas is quite as poisonous to mosquitoes, flies, rats, mice, etc., as the moist gas. Dry sulphur dioxid, however, has absolutely no germicidal value.

Sulphur dioxid tarnishes metals, rots fabrics, and bleaches pigments, especially when moist. Fumigation with  $\text{SO}_2$  may, however, be done with little damage to property on dry days. Metal work, fabrics, and pigments that cannot be removed from the room may be protected from the sulphur fumes by coating with petroleum jelly or covering with paper.

Sulphur dioxid may be produced either by burning sulphur or by liberating liquefied sulphur dioxid. The methods of generating the gas will be found on page 1396. Two pounds of sulphur burned for each thousand cubic feet of air space and an exposure of two hours are sufficient to kill mosquitoes, flies, and other insects in a small tight space; three to four pounds and an exposure of 6 hours are ample for rats and mice. If the space is large or leaky, the amount of gas should be increased and the time of exposure prolonged. See pages 384 and 1396.

*Flowers of Sulphur.*—Sulphur in its dry, powdered state is useful against a number of parasites. In this form, however, it has little

<sup>4</sup>Sulphur cannot be depended upon to kill the eggs of lice, fleas, mites, etc.

use as an insecticide in preventive medicine, not being efficacious against bedbugs, ants, roaches, or fleas.

It may be applied in several ways, the simplest of which is to sprinkle the dry sulphur about the places where insects are found. Flowers of sulphur may also be combined advantageously with other insecticides, such as kerosene emulsion, resin wash, or soap wash. It should first be mixed into a paste and then added to the spray tank in the proportion of about 1 or 2 pounds to 50 gallons. It is very efficacious for the destruction of the mites and rust of plants and fruits.

Sulphur in the form of an ointment is particularly obnoxious to ticks and other ectoparasites. The itch-mite (*Sarcoptes scabiei*) is very susceptible to the flowers of sulphur, which is, therefore, one of the ingredients of almost all ointments used in this skin affection—scabies.

Sulphur dips are used to destroy the mites on domestic animals. The formula now recommended for the treatment of scabies of cattle is as follows: Flowers of sulphur, 24 pounds; unslaked lime, 12 pounds; water, 100 gallons. It is common experience that, while sulphur dips may be depended upon to destroy the mites, they do not destroy the eggs, hence the treatment should be repeated in about 10 days, which permits time for the eggs to hatch and develop into adults. The lime and sulphur dips are widely used for both cattle and sheep affected with scabies. The advantages of this class of dips over arsenical dips are that they are effective, but not poisonous for cattle or man. Lime and sulphur dips are not effective for the Texas fever tick, and arsenic should therefore be used.

**Formaldehyd.**—Formaldehyd, while holding the front rank as a germicide, is a feeble insecticide. The gas seems to have no effect whatever upon roaches, bedbugs, and insects of this class even after prolonged exposure to very high percentages. As a differential poison formaldehyd gas is a very remarkable substance. It destroys bacteria almost instantly, but, while it is irritating to the higher forms of animal life, it is not very toxic. I have repeatedly found that roaches and other insects with strong chitinous protection seem unharmed after 12 hours' exposure to very strong percentages of the gas in air-tight disinfecting chambers. Mosquitoes may live in a weak atmosphere of the gas over night. It will kill them, however, if the gas is brought in direct contact with them in the full strength and time prescribed for bacterial disinfection.

When a weak insecticidal gas is used, it is much more difficult to obtain direct contact between the gas and the insects than between the gas and germs, because the sense of self-preservation aids the former in escaping from the effects of the irritating substance. Mosquitoes and other insects hide in the folds of towels, bed clothing,

hangings, fabrics, and out-of-the-way places where the formaldehyd gas does not permeate in sufficient strength to kill them. The gas tends to polymerize and deposit as paraform on the surface of fabrics which prevents its penetration, and large quantities are lost by being absorbed by the organic matter of woolen fabrics. Mosquitoes have a lively instinct in finding cracks or chinks where fresh air may enter a room or other places where the gas is so diluted that they escape destruction. Therefore, formaldehyd gas, as well as other culicides, cannot be trusted to kill all the mosquitoes in a room which cannot be tightly sealed. On account of its feeble action, formaldehyd should not be used as an insecticide.

For the best methods of evolving formaldehyd gas, the quantities to be used, and other details of the process, see page 1391.

Formaldehyd gas in watery solution, known as formalin, is useful for the destruction of flies. Small quantities of dilute formalin (1.25 to 2.5 per cent.) placed in saucers about the room attract flies. They drink the fluid, which soon kills them.

**Pyrethrum.**—Pyrethrum is a popular and much used insecticide because it is comparatively cheap and non-poisonous to man and the higher animals. It is also non-corrosive, but unfortunately it has but a feeble action against roaches, ants, bedbugs, flies, fleas, mosquitoes, etc. It has no germicidal action.

Pyrethrum, also sold under the names of Buhach or Persian insect powder, or simply "insect powder," is the flowers of the *Chrysanthemum roseum* and the *Chrysanthemum carneum*, both hardy perennials and resembling camomile in appearance. According to Kalbrunner, 4 grains of the pure powder sprinkled on a fly in a vial should stupefy it in 1 minute, and kill it in 2 or 3 minutes. It acts on insects externally through their breathing pores. It may be used either as a dry powder or by its burning fumes. As a dry powder it may be used pure or mixed with flour, in which form it should be puffed about the room, especially into cracks.

When pyrethrum powder is ignited it smolders, giving off fumes which stun, but do not always kill, mosquitoes.<sup>5</sup> It is not, therefore, a dependable insecticide. This uncertainty of pyrethrum restricts its field of usefulness.

Pyrethrum fumes do not corrode metals nor act injuriously upon fabrics and pigments. However, a slight brown deposit is occasionally left on exposed surfaces which may stain linen a yellowish color. This deposit or stain is readily washed out, or soon fades.

Pyrethrum powder has been useful in those cases where sulphur is prohibited on account of the danger of damage to paintings, fabrics,

<sup>5</sup>Tobacco smoke and other substances which produce dense fumes, particularly those containing pyroligneous products, will kill mosquitoes.

tapestries, metal work, musical instruments, upholstered furniture, and the like. It is used in the proportion of 2 pounds per 1,000 cubic feet of air space, the exposure being for not less than 4 hours. As its insecticidal effect is uncertain, it is necessary carefully to sweep up and burn all the mosquitoes that have been stunned and are apparently dead after the fumigation. Most of these mosquitoes will be found on the window sill or on the floor close to the window, where they are attracted by the light in their efforts to find an exit to escape the fumes. Advantage should be taken of this tendency of the mosquito to seek the light by darkening all but one window.

Sheets of paper containing some sticky preparation may be placed upon the floor and upon the window sill in order to catch the mosquitoes. A satisfactory adhesive preparation may be made by dissolving, by the aid of heat, 65 parts of colophony resin in 35 parts of castor oil. This simplifies the collection and disposal of the insects.

Pyrethrum powder should be distributed in pots or pans and set on fire with a little alcohol, which should first be sprinkled over it. The quantity apportioned to any one pot or pan should not exceed 1½ inches in depth, if the exposure is to be for 4 hours. The pots and pans should be set on bricks to prevent scorching the floor.

Much of the pyrethrum upon the market is impure, which further weakens what is a feeble insecticide at best.<sup>6</sup>

**Phenol-camphor** (*Mim's Culicide*).—Camphophenique or phenol-camphor is prepared by rubbing up equal weights of phenol crystals and camphor. It may be more conveniently prepared by first liquefying the phenol by gentle heat and then pouring it over the camphor. The camphor and phenol combine to form a new chemical compound, which remains fluid at ordinary temperatures. When phenol-camphor is moderately heated it gives off dense fumes, which rise rapidly and diffuse slowly, and after 30 to 60 minutes, depending upon the amount employed and the temperature of the air, the fumes condense and are deposited as a slight moisture on all exposed surfaces. As a culicide phenol-camphor is about equal to pyrethrum; the fumes stun the mosquitoes, but do not always kill them. The fumes are somewhat irritating to the mucous membranes, especially the eyes; they may cause dizziness, headache, cloudy urine, and other mild symptoms of phenol poisoning in susceptible individuals much exposed to their inhalation. The fumes of phenol-camphor do not tarnish metals, rot fabrics, or bleach pigments. They, however, have the disagreeable property of softening the varnish of surfaces on which they condense. On account of its slight power of diffusion, relatively high cost, and uncertainty of action, it cannot take the place of sulphur except in the parlor, pilot house,

<sup>6</sup> *Insect Powder*, Bull. 824, U. S. Dept. of Agriculture, 1920.

and other compartments where sulphur is prohibited on account of the damage it produces.

Phenol-camphor is used in the proportion of 4 ounces to every thousand cubic feet of air space, and with an exposure of 2 hours. In this proportion and time the film of condensation is slight and is rapidly dissipated after the doors and windows are opened. The preparation of the room is the same as that described above. The phenol-camphor apportioned to the room to be fumigated should be distributed in agate-ware basins, not more than 8 to 10 ounces to any one basin. Each basin is set over an alcohol lamp at such an elevation and in such a manner as will permit a rapid evolution of the fumes. Care must be taken not to heat the basin so quickly as to cause the liquid to become overheated and take fire. This point must first be determined experimentally for each type of lamp used. One of the small brass alcohol vapor lamps to be found on the market serves excellently. As a safeguard against accidents the lamp should stand in a pan containing about one-half inch of water. The basin containing the phenol-camphor may be set upon a section of galvanized iron stove-pipe, at one end of which sectors are cut out so as to form legs of a length equal to the height of the lamp; just below the upper margin of the pipe a series of holes are punched so as to provide for draft. The stove-pipe should be of such a length as to support the basin containing the phenol-camphor about 10 inches above the flame. This ingenious and simple device, suggested by Berry and Francis, acts as a chimney, protects the flame, is relatively cheap, and has proved satisfactory.

**Hydrocyanic Acid Gas.**—Hydrocyanic acid gas is extremely poisonous to all forms of life. It kills roaches, bedbugs, mosquitoes, fleas, flies, rats, mice, and other vermin with great certainty and very quickly. HCN also kills insect eggs, which sulphur dioxid and other gases fail to do. Hydrocyanic acid gas is not a germicide. It is not very poisonous to the higher forms of plant life. Hydrocyanic acid gas is much used in greenhouses for the destruction of insect pests and for scale and other parasites of fruit trees. The gas has a distinct place in the fumigation of granaries, stables, ships, barns, outhouses, railroad cars, and other uninhabited structures infested with vermin. It is also extensively used in flouring mills against weevils, in railroad cars against bedbugs, and in tobacco warehouses against insects in general. It should be used in the household only with the greatest precaution, as the least carelessness with it would probably mean the loss of human life. It has the marked advantage that it does not harm metals, fabrics, or pigments, and may be used in the most expensive drawing rooms.

Hydrocyanic acid gas is lighter than air and has an agreeable aromatic odor quite familiar in the flavoring essence of bitter almonds. The best method of generating it for the purpose of fumigation is by

the action of dilute sulphuric acid upon potassium cyanid, in the following proportions:

Sodium cyanid	1 ounce	Potassium cyanid	1.0 ounce
Sulphuric acid	1½ ounces	Sulphuric acid	1.0 ounce
Water	2 ounces	Water	2.5 ounces

The first step is to dilute the acid, which is done by adding the acid to water in a vitrified clay jar or receptacle capable of withstanding the heat. The whole amount of cyanid should be put into the acid at once. As the evolution of the gas is rapid, the operator should be ready to leave the spot without delay. As pointed out by Fulton, it is convenient to tie the cyanid up in a bag made of cheese cloth or tissue paper, which is lowered into the acid by a cord passing outside of the room. The amount of gas used for fumigation, expressed in terms of cyanid, is from ½ ounce to 10 ounces per 100 cubic feet of space. From 30 minutes to 2 hours will kill lice, bedbugs and roaches, but in practice an exposure of 2 to 6 hours is advisable (page 514). Hydrocyanic acid gas is quite as effective as sulphur dioxid, is not destructive, is reasonably cheap, and is certain in its action, but its poisonous nature is such a serious drawback that it has a limited place as an insecticide in public health work. It is finding favor in maritime quarantine practice, where it is largely replacing SO<sub>2</sub>. See pages 515 and 1402.

**Bisulphid of Carbon.**—Bisulphid of carbon (CS<sub>2</sub>) is a very efficient insecticide, but a dangerous one, on account of its inflammable and explosive nature. It quickly kills mosquitoes, roaches, flies, ants, and insects of all kinds, as well as rats, mice, and squirrels. When pure it is a mobile, colorless liquid with an agreeable ethereal odor, but often it has a more or less fetid odor from the presence of other volatile compounds. The liquid must be kept in well-stoppered bottles in a cool place, and away from the light and fire. It evaporates rapidly at ordinary temperatures, so that in using this substance in a confined space it is sufficient to pour it into open pans. Carbon bisulphid is very inflammable—more so than ether—and burns with a pale blue flame yielding sulphur dioxid and carbon dioxid or monoxid. In its use every precaution must be taken to see that there is no fire, lighted cigar, etc., in or about the field of operation. On account of its poisonous nature, if used in a house or other inhabited structure, the rooms must be thoroughly aired after its use.

According to Hinds, shallow tin pans or plates make good evaporating dishes for carbon bisulphid. The larger the evaporating area the better. About one square foot of evaporating surface is used to every 25 square feet of floor area, and one-half to one pound of the liquid carbon bisulphid is used for each square foot of evaporating surface.

These figures, of course, are only suggestive and approximate. The pans should be placed as high in the room as possible, since the vapor is so heavy that it settles rapidly. Care should be taken when placing the pans to see that they are nearly level so as to hold the liquid, though ordinarily no particular harm will be done if some of it is spilled. It should not be found necessary to lose time in adjusting such things after the operation has begun.

Carbon bisulphid was extensively used in California in the plague campaign. A piece of waste the size of an orange is saturated with the liquid and the wet ball placed in the mouth of the squirrel hole. Wet clay is then stamped into the warren so that the gas which is generating may have no opportunity to escape. All of the holes of the burrows are treated in this way. In some instances the ball is placed deeply in the hole and then ignited. This is more or less uncertain, as an explosion occurs, and, while the gas is thus disseminated, its action only covers a limited period of time, and is, therefore, not as certain as simply allowing the carbon bisulphid to evaporate. It not only kills the squirrels, but also the fleas on them.

*Carbon tetrachlorid* ( $\text{CCl}_4$ ) may be used in place of carbon bisulphid. It is neither inflammable nor explosive, but somewhat more poisonous than chloroform. The sale of carbon tetrachlorid is forbidden in Paris on account of deaths from its use as a shampoo. It is sold in this country as a cleaning agent.

**Petroleum.**—Petroleum, kerosene, or coal oil is a very valuable insecticide. Petroleum and its products, such as gasoline or naphthalene, are the most dependable insecticides we have, and are used more and more in one form or another.

As a remedy for mosquitoes coal oil is applied in the proportion of about 1 ounce to 15 square feet of water surface. It should form a uniform film over the surface, and will then destroy the larvae and pupae of the mosquito and the adult females coming to the water to lay their eggs. The oil must be renewed every week or two, depending upon the temperature and other conditions. A light grade of fuel oil is best for this purpose. See page 282.

Petroleum is also useful against roaches, bedbugs, fleas, lice, and other insect vermin when used by direct application or by spraying, either in the form of the pure oil or as an emulsion. Petroleum is very efficient against fleas. Frequent application to the floor or other places will keep away ants, and by direct application to the breeding, feeding, and traveling places, it is a useful remedy against household vermin in general. Coal oil is the cheapest and most effective remedy for lice, by direct application to the head or other parts affected.

Emulsion of crude petroleum for application to the skin of animals

or to trees, or other plants, or for general insecticidal purposes is made from the formula of T. M. Price:

Crude petroleum .....	2 gallons
Water .....	1½ gallon
Hard soap .....	1½ pound

Dissolve the soap in the water with the aid of heat. To this add the crude petroleum; mix with a spray pump or shake vigorously and dilute with the desired amount of water. The emulsion of crude petroleum made according to this modified formula remains fluid, and can be easily poured. It will stand indefinitely without any tendency toward separation of the oil and water, and can be diluted in any proportion with cold soft water.

*Gasoline, naphtha, and benzine*, also *naphthalene* are among the best pulicides, and as such are extensively used to kill lice in typhus fever campaigns. See page 368.

**Arsenic.**—The arsenical compounds, according to Marlatt,<sup>7</sup> have supplanted practically all other substances as a food poison for biting insects. The two arsenicals in most common use obtainable everywhere are arsenate of lead and Paris green. Scheele's green, or arsenite of copper, is less known and less easily obtainable, but in some respects is better than Paris green. The use of powdered white arsenic is not recommended on account of its corrosive action, as well as the fact that it is apt to be mistaken for harmless substances.

The arsenical poisons may be applied in one of three ways: (1) in suspension, as poisoned waters, mainly in the form of sprays; (2) as a dry powder blown or dusted about the infested areas; or (3) as poisoned bait.

It must be remembered that the arsenicals are very poisonous; they should be so labeled, and care taken to prevent accidents.

*Paris green* is a definite chemical compound of arsenic, copper, and acetic acid (acetoarsenite of copper), and should have a nearly uniform composition. It is rather a coarse powder, or, more properly speaking, crystal, and settles rapidly in water, which is its greatest fault so far as the making of suspensions of this substance is concerned.

*Scheele's green* is similar to Paris green in color and differs from it only in lacking acetic acid; in other words, it is simply arsenite of copper ( $\text{CuHAsO}_3$ ). It is a finer powder than Paris green, and, therefore, is more easily kept in suspension.

*Arsenious oxid* ( $\text{As}_2\text{O}_3$ ), or white arsenic, commonly known as arsenic, is used in dips to destroy ticks. See page 355.

*Arsenate of lead* is prepared by combining, approximately, 3 parts of the arsenate of soda with 7 parts of the acetate of lead (white sugar

<sup>7</sup> *Farmers' Bulletin No. 19*, U. S. Dept. of Agriculture.

of lead) in water. These substances, when pulverized, unite readily and form a white precipitate, which is more easily kept suspended in water than any of the other arsenical poisons. Its use is advised where excessive strengths are not desirable, and upon delicate plants, where otherwise scalding is likely to result.

An average of one pound of either Paris green or Scheele's green, or London purple to 150 gallons of water is a good strength for general purposes in using the wet method. The powder should first be made up into a thin paste in a small quantity of water, and, if the suspension is to be used upon plants, vegetables, or about foliage, an equal amount of quicklime should be added to take up the free arsenic and remove or lessen the danger of scalding.

For the distribution of dry poison the arsenicals are diluted with 10 parts of flour, lime, or dry gypsum.

The following mixtures are used in the form of sprays, to destroy insects and fungi upon plants.<sup>8</sup> The arsenate of lead mixture has been much used in Massachusetts with success against the gipsy moth and other destructive insects upon trees and plants. These mixtures are equally useful as insecticides wherever sprays or local applications are practicable.

#### ARSENATE OF LEAD

Arsenate of soda (5 per cent. strength), 4 ounces.

Acetate of lead, 11 ounces.

Water, 100 gallons.

Put the arsenate of soda in 2 quarts of water in a wooden pail, and the acetate of lead in four quarts of water in another wooden pail. When both are dissolved, mix with the rest of the water. Warm water in the pails will hasten the process. For the elm-leaf beetle use 10 instead of 100 gallons of water.

A number of ready-made arsenates of lead are now on the market, and, except when very large amounts are needed, it will probably prove cheaper to buy the prepared material than to make it. With this ready-made material use 3 pounds to 50 gallons of water for codling moths, and 5 pounds to 50 gallons for the elm-leaf beetle and on potatoes.

#### ARSENATE OF LIME

White arsenic, 2 pounds.

Sal-soda, 8 pounds.

Water, 2 gallons.

<sup>8</sup>From *Bulletin No. 123*, April, 1908, of the Massachusetts Agricultural Experiment Station by Stone and Fernald.

Boil till the arsenic all dissolves—about 45 minutes. Make up the water lost by boiling and place in an earthen dish. For use take one pint of this stock, 2 pounds freshly slaked lime, and 45 gallons water, and spray.

#### KEROSENE EMULSION

Hard soap, shaved fine,  $\frac{1}{2}$  pound.

Water, 1 gallon.

Kerosene, 2 gallons.

Dissolve the soap in the water, which should be boiling; remove from the fire and pour it into the kerosene while hot. Churn this with a spray pump till it changes to a creamy, then to a soft, butter-like mass. Keep this as a stock, using one part in nine of water for soft-bodied insects, such as plant lice, or stronger in certain cases.

#### RESIN-LIME MIXTURE

Pulverized resin, 5 pounds.

Concentrated lye, 1 pound.

Fish or other animal oil, 1 pint.

Water, 5 gallons.

Place the oil, resin and one gallon of hot water in an iron kettle and heat till the resin softens; then add the lye and stir thoroughly; now add 4 gallons of hot water and boil till a little will mix with cold water and give a clear, amber-colored liquid; add water to make up 5 gallons. Keep this as a stock solution. For use take:

Stock solution, 1 gallon.

Water, 16 gallons.

Milk of lime, 3 gallons.

Paris green,  $\frac{1}{4}$  pound.

#### BORDEAUX MIXTURE

Copper sulphate (blue vitriol), 4 pounds.

Lime (unslaked), 4 pounds.

Water, 25 to 50 gallons.

Dissolve the copper in hot or cold water, using a wood or earthen vessel. Slake the lime in a tub, adding the water cautiously and only in sufficient amount to insure thorough slaking. After thoroughly slaking, more water can be added and stirred in until it has the consistency of thick cream. When both are cold, dilute each to the required strength and pour both together in a separate receptacle and thoroughly mix. Before using, strain through a fine mesh sieve or a gunny cloth; the mixture is then ready for use.

If the amount of lime in the Bordeaux mixture is insufficient there is danger of burning tender foliage. In order to obviate this, the mixture can be tested with a knife blade or with ferrocyanid of potassium (1 oz. to 5 or 6 oz. of water). If the amount of the lime is insufficient, copper will be deposited on the knife blade, while a deep brownish-red color will be imparted to the mixture when ferrocyanid of potassium is added. Lime should be added until neither reaction occurs. A slight excess of lime, however, is desirable, and it is seldom one has to apply these tests. The Bordeaux mixture is a good fungicide, but is less useful as an insecticide.

The abundant and increasing use of the salts of lead, arsenic and copper to spray fruits, berries, and vegetables of all sorts has opened a new question, as these substances are poisonous for man. Ordinarily, an apple will carry about 0.5 mgm. of arsenate of lead. However, as much as 5 mgm. has been found on the surface of an apple directly after spraying. One quarter of a quart of strawberries may carry as much as 8 mgm. of oxid of arsenic. A head of cabbage may carry a relatively large amount especially on the outer leaves. The importance of thoroughly washing all fruits, vegetables, and berries is again emphasized.

## MOSQUITOES

Mosquitoes differ markedly in their habits. Some species may be classed as domestic animals because they are commonly or almost exclusively found in or close to human habitations. This is notably the case with *Stegomyia calopus*, the yellow fever and dengue mosquito; *Culex quinquefasciatus fatigans*, the intermediary for *Filaria bancrofti* (filariasis). The sylvan or wild mosquitoes, of which the *Culex sollicitans*, the common salt marsh mosquito of our Atlantic coast, is a well-known example, are seldom met with in human habitations. A third or semi-domestic class may be encountered either in or near houses, or in fields or swamps. This class includes the malarial mosquitoes belonging to the genus *Anopheles*.

The adult mosquito may be carried to considerable distances by winds; but of its own volition it does not ordinarily travel outside of a radius of half a mile from its breeding place. The longest flights noted by le Prince are about a mile. Most species do not fly nearly so far. This means that the destruction of all breeding places within a comparatively small radius of a habitation will rid it of all but those mosquitoes which are blown in by the winds from more or less distant marshes, or which are brought in the vessels and vehicles of trade and travel.

**Life History and Habits.**—Mosquitoes pass through four stages: (1) the egg or embryo, (2) the larva, (3) the pupa, and (4) the imago or adult winged insect. The egg, larval, and pupal stages are aquatic. Mosquitoes never breed in damp grass, weeds, or bushes, as is popularly supposed, but the winged insects frequently rest and hide in vegetation. The different species of mosquitoes not only differ markedly in their habits, but differ considerably in the character of their breeding places. The domestic species, such as the yellow fever mosquito and *Culex pipiens*, may be found breeding in any collection of water in or about houses. Thus, they have been found in discarded tin cans, bottles, and broken crockery on the garbage heap; in buckets, tubs, barrels, cisterns, and wells; in baptismal fonts; in flower pots and sagging roof gutters; in street and roadside puddles, gutters, and ditches; in cesspools and sewers.

The semi-domestic mosquitoes, to which the malarial-bearing insects belong, may occasionally be found breeding in tin cans, barrels, hoof prints, post holes, and hollows in trees or tree stumps, but they usually prefer grass-bordered pools, slowly flowing ditches, the margins of lakes and streams, even such as are stocked with fish, provided the margins are shallow or are more or less choked with reeds and water plants so that the fish cannot reach them. Some species of *Anopheles* breed freely in the grassy edges and eddies of fairly free running clear brooks. The sylvan or wild mosquitoes select breeding places of much the same character as do the semi-domestic species, with which they are not infrequently found associated, except that such breeding places are more or less remote from human habitations, in woods, swamps, and fresh or salt (brackish) coastal marshes.

Male mosquitoes are vegetarians. The females of many species have developed a taste for blood, and, indeed, blood has become indispensable to nearly all for the full development of their eggs. This is the case with *Stegomyia calopus*. Remembering how all-important the generative instinct is, we can now well understand why the yellow fever mosquito, for example, will, when disturbed, return again and again in an endeavor to obtain her fill of this life-giving fluid.

The mosquito usually lays her eggs upon the surface of the water, and these, depending upon the species, either float separately on their sides (*Stegomyia* and *Anopheles*), or adhere together in irregular, raft-like masses (*Culex*). In a day or two, under ordinary conditions, the eggs hatch out into larvae or "wiggle-tails." Although the larva is an aquatic animal, it is a true air-breather. The larva of *Anopheles* ordinarily rests and feeds at the surface, where it lies in an almost horizontal position, its tail and dorsal bristles touching the surface film, while it breathes through a breathing siphon, which is very short and insignificant in appearance.

The larvae of the other species move about more or less, actively searching for food, but at intervals of a minute or two they may be seen to come to the surface for air, where they hang, head down, attached by their more or less prominent conical breathing tubes to the surface film. The mosquito remains in the larval stage about a week—the length of time varying with the species, and for any species with the temperature; and is then transformed into a curiously shaped creature known as the pupa.

The pupa has no mouth and does not feed. It remains quietly at the surface except when disturbed. It breathes through a pair of trumpet-shaped tubes, which project from the dorsum of the throat. The pupal stage usually lasts two or three days, and is terminated by the emergence of the adult winged insect (imago) from its pupal case through a rent in the region of the breathing tubes.

The time from the laying of the egg to the winged insect may, therefore, be as short as nine days. The time depends upon the temperature and the abundance of the food supply. Warmth favors and cold retards; therefore, mosquitoes are most abundant during the summer, late spring, and early fall months in our climate. In the tropics the wild species become more abundant during the wet season.

The way in which mosquitoes manage to pass through the rigors of the winter probably varies with the different species. Some, like the malarial *Anopheles*, hide in sheltered cellars or dark nooks, or hibernate in other out-of-the-way places. Other species survive through the power of the larva or egg to resist cold, for the larvae or eggs of some species will hatch even after they have been frozen.

### *THE DESTRUCTION OF MOSQUITOES*<sup>9</sup>

The measures aimed at the destruction of the mosquito naturally fall into two classes: (a) those directed against the egg, larva and pupa—the aquatic stages—and (b) those directed against the winged insect.

For the extermination of mosquitoes the most effective measures are those which destroy their breeding places, and thus prevent their multiplication. For the best results, both individual and communal effort are necessary, but the importance of individual effort alone cannot be too much emphasized. The individual, by attacking the problem on his own premises, grounds, or estate, can not only do much to rid his own immediate neighborhood of mosquitoes, and thereby increase his own comfort and guard against disease, but the example thus set will perhaps stimulate his less enterprising neighbors.

<sup>9</sup> Le Prince and Orenstein: *Mosquito Control in Panama*. J. P. Putnam's Sons, New York, 1916.

To insure success it is important to know the habits and breeding places of the particular species that it is desired to suppress.

**Natural Breeding Places.**—Natural collections of water which may serve as breeding places are best dealt with by filling in or by draining. In this way they are disposed of once for all. For filling, inorganic refuse, such as cinders and ashes, may be employed, or sufficient earth may be dug from a nearby knoll or hill, care being observed that in so doing a depression capable of holding water is not made. Low marshy lands adjacent to rivers, lakes, or the sea may be filled by pumping silt or sand.

When filling is not practicable, good and permanent results may be obtained by drainage. As a rule, the draining of ponds, pools, or marshes is the simpler and cheaper method. By the draining of marshes is meant the draining of the pools of stagnant water, or in the case of coastal marshes the draining of the stagnant fishless pools that are beyond the reach of the ordinary tides; it does not necessarily include the draining of the water-soaked soil itself. The underdraining of wide acreages of our arable land in the Middle West has been very effective in suppressing the malarial mosquito. Marshy lands may be drained simply by means of ditches. These must be dug of depth sufficient completely to empty the pools under treatment and have sufficient fall to prevent stagnation in the course of the ditch itself. Where a sufficient fall is not obtainable, fishless pools may be connected with those containing fish or with a neighboring stream, so that the fish may freely enter. Mosquito breeding places in the pools in coastal marshes may be suppressed by connecting them with tide water, so that they may be freely scoured by the daily tides. Ditches should have straight sides and must be inspected at frequent intervals, and care must be taken to see that they do not become choked.

Fish are among the most effective of the natural enemies of the mosquito. The fish may be admitted to ponds and pools in the manner just described, or the ponds, pools, ornamental lakes, and fountains may be directly stocked with minnows or gold fish. The margins of pools, rivers, and other bodies of water must be kept free of reeds and water plants, so as to permit the fish to reach the edges—a favorite breeding place for mosquitoes. In still waters, fish are much more effective than in free-running streams. One of the very best means of clearing the land of the numerous small natural collections of water is to place it under cultivation.

When radical measures, such as filling in or draining, are not practicable, resort may then be had to coal oil. Coal oil upon the surface of the water acts by poisoning and also by suffocating the larvae and pupae. A light quality of oil should be used,<sup>10</sup> and it may be poured

<sup>10</sup> The best oil for the purpose is known to dealers as "Fuel oil 29-31."

upon the surface from an ordinary sprinkling pot, or the surface may be sprayed with a hose. Along the banks of ponds, lakes, and slowly moving streams with shallow margins containing vegetation, which offer favorite breeding places for the mosquito, the oil may be applied with a mop. This practice is laborious, but effective. Sufficient oil should be used to cover the entire surface with a thin film. As the oil is volatile, it may disappear within a few days. Furthermore, the film, which should be intact to be effective, may be broken by winds. A strong wind will blow all of the oil to one side, thereby largely defeating the object desired. It is, therefore, important to repeat the oiling regularly at intervals of about one week or 12 to 14 days for *Anopheles*. Oiling, though fairly effective when properly carried out, is only a temporary expedient, and in the end is rather expensive. See also page 275.

The Panama larvicide is made as follows: 150 gallons of crude carbolic acid having a specific gravity not greater than 0.97 and containing not less than 30 per cent. tar acids, is heated in an iron tank with a steam coil to a temperature of  $212^{\circ}$  F., then 200 pounds of powdered or finely broken common resin is poured in. The mixture is kept at a temperature of  $212^{\circ}$  F. Thirty pounds of caustic soda dissolved in 60 gallons of water are then added, and the solution is kept at the same temperature until a perfectly dark emulsion without sediment is formed. The mixture is thoroughly stirred from the time the resin is added until the end. One part of this emulsion to 10,000 parts of water is said to kill *Anopheles* larvae in less than half an hour, while 1 part to 5,000 parts of water will kill them in from 5 to 10 minutes.

The Panama larvicide is mixed with 5 parts of water and sprayed upon pools or along the banks of streams. This larvicide added to 5 parts of crude petroleum favors its spread upon the surface of the water. A good method is to place the mixture in a barrel and permit it to drip upon the surface of the stream or pond to be treated.

Other larvicides that may be used in non-potable water are: sulphuric, hydrochloric, and other acids, potassium permanganate, sulphate of copper, sulphate of iron, bichlorid of mercury, carbolic acid, anilin products, or coal tar. They must be used in relatively large amounts to be effective, and frequently renewed according to circumstances. Probably the most practical larvicide for water barrels is "nitre cake," a by-product of powder and dynamite factories—one pound to a barrel.

No body of water is too small for a mosquito nursery. They breed in puddles by the roadside; in water that accumulates in furrows in gardens or fields, especially in clayey soil; in street gutters and house gutters; in holes in rocks; in hollows of trees, in pitcher plants, or anywhere that a gill of water is allowed to stand.

**Artificial Breeding Places.**—The permanent elimination of artificial breeding places for mosquitoes in a city depends first of all upon providing a good quality and sufficient quantity of potable water by means of a modern closed system. This will permanently do away with the necessity of cisterns, barrels, and tubs for the storage of water about the premises. When domestic storage is a necessity, care must be taken to prevent the mosquito from gaining access to the water. The water barrels should be provided with tightly fitting covers. Burlap, sheeting, or several thicknesses of cheese-cloth, or, better, wire screening held in place by a well-fitting hoop, serve this purpose very well. Wooden covers are unsatisfactory, for they rarely fit accurately enough to keep out the mosquito, and this defect is enhanced by the warping of the wood, which usually makes an old cover worse than useless. More satisfactory than the wooden cover is one made of light galvanized sheet iron, the central portion of which may be made of wire gauze. The rim of the barrel should be trimmed to remove any irregularities that might prevent the cover from fitting evenly all around. Whatever the form of the cover employed, it should not be removed except for cleaning or refilling the barrel. The water should be drawn from a spigot. Where the water is very turbid and must undergo sedimentation before being used, several barrels should be provided for its storage and the water used from each barrel in turn. In such a case the spigot should be placed about a foot from the bottom, so that the sediment need not be disturbed as the water is drawn off for use. Wells should be provided with tight covers and the water drawn by pumps.

Cisterns and tanks should also be provided with accurately fitting covers, and should be inspected frequently for seams and cracks resulting from warping and shrinking of the wood. To guard against this loophole, wire gauze should be used to screen the joint between the tank and its cover. The gauze should include about one foot of the tank and overlap well upon the cover. The inlet to the tank or cistern should be provided with a cap of copper meshed wire gauze which may be protected by another and coarser meshed cap of stout wire, to prevent its choking with leaves, etc. As an additional precaution, the inlet pipe should stop above the top of the cistern, discharging its water on to the gauze part of the cover. In cases of emergency, as in times of epidemics of yellow fever or dengue, where the permanent measures for preventing mosquito breeding have been neglected, the surface of the water in barrels, tanks, and cisterns may be covered with some neutral non-volatile oil which does not impart a taste to the water.

Cesspools and privy vaults should be done away with and replaced with dry earth closets or a water carriage system. Where this has not been done they may be frequently and copiously oiled.

Among the artificial breeding places for mosquitoes may be men-

tioned chicken-pens in poultry yards; water cups on the frames of grindstones; baptismal fonts; tin cans or broken bottles in back yards; the catch basins of sewers; the water that stands in sagging house gutters; flower-pots, fire buckets, and similar places.

**Screening.**—Mosquito screens are the obvious and most effective single measure for personal prophylaxis where disease-carrying mosquitoes exist. In order to be effective the screening must be intelligently carried out with careful attention to details. The screen itself must be sufficiently close to keep out the mosquitoes. Some of them are able to squeeze through surprisingly narrow chinks. I was able to demonstrate, in the experimental work at Vera Cruz, that the *Stegomyia* mosquito can pass a metal wire screen containing 16 strands or 15 meshes to the inch, but cannot pass one containing 19 strands or 18 meshes to the inch. When the screen consists of a fabric which is apt to pull out of shape so that some of the meshes are larger than others, it is advisable to use a net woven closer than 20 strands to the inch. Experience in malarial and yellow fever districts has taught this lesson, so that it is customary in those countries to use a rather closely woven material resembling nainsook. Metal screens made of iron wire are cheapest only when first cost is considered. They hardly last a season unless painted, in which case the size of the mesh is considerably reduced and interferes with ventilation, a serious objection in hot weather or a tropical climate. Mesh made of galvanized iron wire has a greater durability. Screens made of brass or bronze are expensive, but cheap in the long run, as they last almost indefinitely.

The screening should include the entire house, or at least those parts that are occupied. In the tropics it is better to screen the "galleries" than each individual window. In any case, frequent and repeated inspection should be made to discover breaks in the screen or openings due to warping of the woodwork. Care must be exercised not to overlook fireplaces, ventilators, and other openings. The door should be guarded by a screened vestibule of such a depth as to make it impossible for a person to hold both doors open at the same time. The screen door should open outward and, if possible, should be exposed to the direct sunlight during the day, without vines or nearby vegetation of any kind to protect and lodge the mosquitoes. During the night the door should not be in an artificial light, which attracts many mosquitoes. An electric fan directed outward is a very good device to prevent mosquitoes flying through the doorway. In addition, a whiskbroom or feather duster should hang in the vestibule to brush off the insects that may rest upon the clothing. A screened house is safe only to careful and intelligent people.

In addition to screening the house, mosquito bars over the bed will be found necessary in mosquito-infested places. It is best to suspend the mosquito bar from the ceiling and carefully gather the bottom together

so as to keep the insects out during the day time. At night the bar should be carefully tucked in around the bed so as to leave no openings. Mosquitoes have no trouble in biting through the meshes of the bar, provided a restless sleeper comes close enough to it.

Persons who are required to go out at night in a malarious district, or who must expose themselves during yellow fever times, may screen themselves effectively with a veil of mosquito netting hanging from a broad-brimmed hat to the shoulders and chest. The hands and wrists may be protected with gloves, and the ankles with leather leggings or other suitable mechanical device.

**Volatile Substances.**—Spirits of camphor, oil of pennyroyal, and other volatile substances, such as oil of peppermint, lemon juice, or vinegar, rubbed upon the face and hands, or a few drops on the pillow at night, may keep mosquitoes away only for a time. Oil of citronella is one of the best known substances used in this way. Ordinarily a few drops on a bath towel hung over the head of the bed may keep some mosquitoes away. When they are very abundant and persist, a few drops rubbed on the face and hands may be tried. All these substances soon lose their efficiency; none of them last until morning.

The diseases known to be conveyed by mosquitoes are: malaria (*Anopheles* spp.), yellow fever (*Stegomyia calopus*), filariasis (*Culex* and *Anopheles*), dengue (*Stegomyia calopus*), and doubtless others.

### MALARIA

Malaria is one of the most prevalent of all preventable diseases; it is the scourge of the tropics. The cause of this infection was one of the first to be discovered (Laveran, 1880), and its mode of transmission was one of the most brilliant discoveries in sanitary science (Ross, 1895). Despite the fact that we have more exact knowledge of malaria, considering the difficulties of the subject, than perhaps any other disease, despite the fact that we have accurate means of diagnosis and a ready cure, and despite the fact that we have assured measures of prevention, malaria counts its victims by the hundreds of thousands annually. In geographic distribution malaria extends from the Arctic circle to the Equator, but becomes more virulent the warmer the climate.

There are probably a million cases of clinical malaria in our southern states each year—and the carriers far outnumber the cases. The distribution is very unequal, but chiefly rural. Wherever malaria prevails, and almost in direct proportion to its prevalence, the population is generally subnormal physically, mentally and economically.

At least three separate malarial parasites of man are known, namely: (1) *Plasmodium malariae* (Laveran), quartan fever; (2) *Plasmodium vivax* (Grassi and Feletti), tertian fever; and (3) *Plasmodium falcip-*

*arum* (Welch), estivo-autumnal or tropical malaria. These are closely allied hematocytozoa or blood parasites. They produce diseases with well-defined clinical differences, but having the same etiology and mode of transference, so that, as far as prevention is concerned, they may be regarded as one infection.

Many species of animals have a malarial-like infection closely resembling malaria in man; for example, Texas fever of cattle, piroplasmosis of dogs and sheep, proteosoma of birds, etc. So far as is known, no other animal than the *Anopheles* mosquito is subject to the malarial parasites pathogenic for man. Both man and the mosquito are necessary to complete the life cycle of the plasmodium. Man is the intermediate host harboring the asexual phase, and the mosquito is the definitive host harboring the sexual phase of the life cycle of the plasmodium.

**Mosquito Transmission.**—It is now definitely known that in nature malaria is transmitted only by the bite of the *Anopheles* mosquito.<sup>11</sup> Experimentally, the infection may be transferred by injecting blood (containing the parasites) of one person into the blood of another. Nearly 2,000 years ago Varro and Columbella mentioned the possibility that the disease was transmitted by mosquitoes. In Africa some savage tribes call malaria the “mosquito disease.” In 1848 Nott, of New Orleans, considered the matter proved from biological analogies. In 1882 King, of Washington, vigorously advocated the mosquito theory based upon philosophical deductions but no proof. In 1884 Laveran suggested mosquito transmission as probable. In 1894 Manson elaborated the mosquito theory and inspired Ross, of the Indian Army Medical Service, who in 1895 demonstrated that the crescents of estivo-autumnal malaria undergo changes in the mosquito. In 1896 Bignami advocated the theory and compared it to the transmission of Texas fever by the tick. In 1897 Ross published further convincing observations upon the development of the estivo-autumnal parasite in the mosquito. In 1897 MacCallum observed an important missing link in the life cycle by observing the flagellum of the microgametocyte (male) fertilize the macrogametocyte (female) with the formation of the vermicle. These observations were made upon *Halteridium* or malaria of birds; later he saw the same phenomenon in estivo-autumnal malaria. The life cycle of the malarial parasite has been confirmed by Daniels, Koch, Grassi, Bignami, Celli, Manneberg, Schaudinn, and many others.

Further evidence that malaria is transmitted by the mosquito was furnished by Sambon and Low, of the London School of Tropical Medicine, and Dr. Terzi, who lived during the three most malarial months of

<sup>11</sup> The subfamily *Anophelinae* has been divided by Theobald (1901) into several genera: *Anopheles*, *Myzomyia*, *Cellia*, *Myzorhynchus*, *Nyssorhynchus*, *Pyretophorus*, etc. This classification serves no useful purpose and is unnecessary.

1900 in Ostia, a very malarial locality of the Roman Campagna. These observers escaped infection simply by keeping within their well-screened huts from before sundown until after sunrise. The final proof was furnished in 1900 by Dr. P. Thurber Manson and Mr. George Warren, who were bitten by infected mosquitoes forwarded from Italy in cages to London.

In the United States, malaria probably hibernates in man and not in the mosquito. Mitzmain<sup>12</sup> believes man the sole winter carrier of ma-

FIG. 22.—*ANOPHELES PUNCTIPENNIS*.

laria in our southern states, and the new crop of mosquitoes are infected in the spring from the gametocytes in the blood of malarial carriers. Hence the importance of starting preventive measures in the winter or early spring.

**The Malarial Mosquito.**—At least twenty-five species, in six genera of the subfamily *Anophelelinae* are more or less definitely known to carry malaria.<sup>13</sup> In Europe *Anopheles maculipennis*; in tropical America *A. argyrotarsus* or *albipes*; in temperate America, *A. quadrimaculatus*, which is probably the same as

*A. maculipennis*, also *A. punctipennis* and *A. crucians*; in India *A. sinensis*; in Africa *A. costalis* are the chief culprits. Darling<sup>14</sup> found that 70.8 per cent. of *Anopheles albimanus* induced to bite malarial patients became infective, while with *Anopheles pseudopunctipennis* only 12.9 per cent. could be infected.

The *Anopheles* mosquitoes are brownish and rather large. They may be distinguished by the fact that the palpi in both the male and the female are at least as long as the proboscis. Only the female transmits the infection. It sits more or less at right angles upon the wall, the head, thorax, and abdomen being in a straight line. Contrary to the yellow fever mosquito, the malarial mosquito is nocturnal in its habits and breeds chiefly in the open ponds, puddles, and natural collections of water in the woods, fields and swamps.

<sup>14</sup> Darling, Samuel T. Transmission of Malarial Fever in the Canal Zone by *Anopheles* Mosquitoes. *Jour. A. M. A.*, 1909, LIII, pp. 2051-2053.

The mosquito becomes infected upon drinking the blood containing the micro- and macro-gametocytes. It requires about twelve days before the sporozoites appear in the salivary glands of the insect. It cannot, therefore, transmit the infection to another person until the lapse of this extrinsic period of incubation. The infected mosquito may live a long time and infect more than one person successively. The malarial parasite does not seem to harm the mosquito.

The parasite will not develop in the mosquito when the mean temperature is below 60° F.

They can, however, survive at much lower temperatures for a short time. King<sup>15</sup> has shown that the tertian parasite is able to survive exposure to a temperature of 30° F. for 2 days; 31° F. for 4 days; and a mean temperature of 46° F. for 17 days. The sporonts of the estivo-autumnal parasite have resisted 35° F. for 24 hours.

None of the Anophelinae are "domestic" in the sense of our house mosquitoes, such as *Culex pipiens*, *C. quinquefasciatus* and *Aedes calopus*, and this is not necessary for the transmission of malaria. The long presence of the malarial parasite in the human circulation, and the consequent frequent opportunity for the mosquito to acquire the infection from carriers compensates for a very loose association between man and insect.

**Immunity.**—A person who once has had malaria seems more apt to have subsequent attacks. Often there appears to be an increased susceptibility rather than an immunity, although these subsequent attacks may be relapses. However, repeated infections, during early life, leave a pronounced resistance. In malarious regions many children carry the parasites in their circulating blood without any manifestations of the disease. These carriers are important factors in spreading the infection in endemic areas, and must be taken into account in preventive measures. In endemic regions carriers far outnumber the cases. It requires much more quinin to sterilize a carrier than to cure a clinical case.

There is no true racial immunity in this disease. Practically all persons who receive the infection for the first time are susceptible. The freedom from malaria which some persons seem to enjoy may be accounted for partly by the fact that mosquitoes seldom bite such persons. It is well known that on account of the odors, or what not, mosquitoes do not bother certain individuals. No doubt the infection of a small number of parasites is often overcome largely through a vigorous phagocytosis.

Individual resistance varies in different individuals and in the same individual at different times. The parasite may remain latent in the spleen or other organs for years. Exposure, overeating, fasting, overwork, or worry, or anything that lowers the vitality of such individuals

<sup>15</sup> *Journ. Exp. Med.*, March 1, 1917, XXV, No. 3.

predisposes to an attack of malaria. The disease often breaks out in persons in good health leaving a malarial region for a health resort, whether mountain or seashore. I was enabled to confirm this observation upon the returning transports from Cuba following the Spanish-American war, when many cases of malaria broke out among the troops previously in good health upon exposure to the cold winds about Cape Hatteras. Personal prophylaxis, therefore, includes careful attention to personal hygiene.

**Prevention.**—The successful suppression of malaria requires a combined attack upon the mosquito and the parasite in the human host. Ultimate success rests upon the suppression of the mosquito. Immediate relief is most quickly gained by measures directed against the infection in man. Screening and quinin prophylaxis, while practical, are only temporary measures.

Celli <sup>16</sup> found that although the destruction of mosquitoes is possible in the laboratory and in small areas, the difficulties in extensive areas are generally insuperable.

Harris maintains that the most practical measure at this time in the crusade against malaria is the radical cure of those harboring parasites. Every person cured means one less focus of infection. Koch and Celli, in 1900, urged that the best way to deal with malaria in the island of Mauritius would be to leave the mosquito alone and to cure the human patients from whom the insects become infected. By the use of this method Ross tells us that Stephensport in New Guinea was cleared of malaria in a few months. The method has also been successful at Lonoke, Arkansas (by Geiger), and in the Yazoo Delta, Mississippi (by Bass). Good results with both methods have been obtained by the Public Health Service and also by the International Health Board.

Le Prince <sup>17</sup> demonstrated that at Gatun *Anopheles* will fly great distances. Le Prince and Griffith registered flights of a mile in South Carolina by *A. quadrimaculatus* from breeding places producing profusely. This was confirmed by Geiger in Arkansas and by Metz for *A. crucians* in Alabama. There is, however, very little doubt that in the majority of places malaria is a local infection; that is, the mosquitoes acquire the gametes and transmit the sporozoites within a restricted area.

The maximum malarial rate is at its height at or toward the end of the warm season, because warmth over 60° F. favors the development of the parasite within the mosquito. The best time to attack the para-

sites in man is during the winter and early spring so as to prevent infection of the new summer brood of mosquitoes.

*Measures Directed against the Mosquito.*—If the breeding of Anophelinae mosquito could be stopped malaria would cease. Mosquito suppression is fundamental and radical. The best way to abolish the breeding places of malaria mosquitoes is to fill up low places or to dry the surface of the land with drains. These two measures hold first place as permanent work. The underdraining of large areas of our arable land of the Middle West with tiled drain has been very effective in suppressing malaria. Open ditches properly constructed and cared for are likewise effective. In the tropics the ditches should be lined with cement, on account of the luxuriant vegetation which soon interferes with their efficiency or may actually convert them into breeding places. The open ditches are much the cheapest in first cost, but not when maintenance is reckoned. The draining of swamp lands is an engineering problem in which the economic factor looms large. One of the very best means of destroying the breeding places of the malaria mosquito is to clear the land and to keep it under cultivation.

When drainage is not practical, the number of mosquitoes may be kept down by introducing fish into the pools, streams, ditches, and other collections of water. Upon limited water surfaces the larvae may be killed with a film of coal oil or the Panama larvicide (page 283).

Large open spaces cause the destruction of a number of mosquitoes, as they cannot live long in the hot sun; therefore, clearing the brush and high grass, which furnish shelter to the insects, aids in preventing wild mosquitoes approaching dwelling houses.

Bats are natural enemies of mosquitoes and should therefore be protected.<sup>18</sup>

The use of screens and culicides has already been referred to (pages 268 and 285).

The best time to begin antimosquito measures is as early in the spring as possible.

Wickliffe Rose states that for the average town in our southern states having a thousand or more inhabitants and a reasonably high infection rate, malarial control by antimosquito measures is economically feasible and a sound business investment.

*Personal Prophylaxis.*—Persons visiting or residing in a malarious region should be particularly careful not to expose themselves at night time. The experience of Sambon and Low on the Roman Campaigna (page 287) is instructive and should be imitated. The location of the residence is important. In a city it should be a reasonably safe distance from the native quarter, because the infection is there most concentrated; but not in the suburbs. The dwelling should, if possible,

<sup>18</sup>Howard, L. O.: *U. S. Public Health Reports*, 35, July 15, 1920, p. 1789.

face the trade winds. A row of tall trees will partly screen the house from the swamp, but the trees must not be too close, else they will furnish shelter for the insects. The house should be on high land if practicable, as it is an old observation that the malarial mosquito does not fly high. People living upon the second floor are less apt to contract the infection than those who sleep on the ground floor. If it is necessary to go out in the night time, one may protect himself by the use of gloves and mosquito netting hanging from the helmet to the shoulders. Care must be taken to guard the ankles against mosquito bites. As all these measures require much time and attention to details, they are usually not efficient in actual practice. Therefore, quinin prophylaxis is much used.

*Quinin Prophylaxis.*—Theoretically the administration of quinin to healthy individuals for the prevention of malaria is not an ideal method of prophylaxis, for it does not prevent infection, but only destroys the parasites in the blood during the period of incubation; practically it is cheap and effective. It should be remembered that quinin kills only the young and tender forms of the plasmodium, and has no influence upon the crescents. Quinin prophylaxis is indicated in proportion to the difficulty of pursuing more permanent methods. It is especially valuable where screens and mosquito bars are not available, as in camping, marching, traveling, or where the occupation takes one out at night. When residents of non-malarial countries go into malarial localities, especially in the rural districts, for short periods of time, quinin is a valuable preventive.

A farmer may not be able to drain and clear his land so as to get rid of mosquitoes; he may not be able to screen his house and keep his screens in order, but he will always be able to buy the amount of quinin which will protect his family from fever, especially as it may cost no more to prevent malaria than it would to cure it—maybe less. Quinin prophylaxis is not so good a method as suppressing mosquitoes, but in many communities this is impracticable; it is not so good as screening, carefully watched, but this is also impracticable in many rural communities.

The systematic use of quinin as a prophylactic on a large scale is of recent origin. The government of Italy in 1902 began the sale of quinin at cost price to communities and towns, which agreed to distribute it gratuitously to those unable to purchase it. In 1903 the towns, etc., were obligated to issue it free of cost to poor people for prophylactic use. The next year, 1904, it was ordered to be given to all working people for use in this way. This is a beneficent public health measure comparable to the free distribution of antitoxin and vaccine virus. There has been a great diminution in the amount of malaria among the farming people of Italy since the introduction of quinin prophylaxis; further-

more, the reduction has been progressive—increasing as the people learn its value.

To be effective as a preventive of malaria, quinin must be taken in sufficient doses during the entire malarial season. The size of the dose and the interval at which the prophylactic is administered are of the utmost importance. There are two principal methods of administration: the one, canonized by Koch, consists of large doses at considerable intervals; the other, used in Italy, consists of smaller daily amounts. Koch advised 16 grains (one gram) of quinin every sixth and seventh day, or every seventh and eighth day, eighth and ninth, ninth and tenth day, according to the danger of the infection. This manifestly leaves several intervening days in which there is no quinin in the circulation. The method has been eminently successful in the very malarious districts of German West Africa, and also in the hands of the Japanese in Formosa. There are several modifications of Koch's method. Plehn advises 8 grains every five days; this amount may even be taken twice a week.

Ziemann gives a gram of quinin sulphate every four days. The alkaloid is administered in solution with 5 drops of hydrochloric acid early in the morning or about one and one-half to two hours after a meal. A convenient rule is to give a dose on the first of the month and thereafter on each day of the month divisible by 4. By this method the alkaloid is probably constantly in the circulating blood.

The administration of small doses of quinin daily is the oldest method of giving quinin as a prophylactic. The amount varies from  $1\frac{1}{2}$  to 7 grains daily. In Italy the average amount is 5 to 7 grains of sulphate of quinin daily, and half that amount for children under 10 years. For children the tannate of quinin made up into chocolates is recommended. The tannate of quinin contains only about half the amount of quinin found in the sulphate, therefore about 5 grains of the tannate is the equivalent of  $2\frac{1}{2}$  grains of the sulphate.

On the Isthmus of Panama good results have been obtained by the use of moderate doses, 3 to 6 grains per day. When the disease increases in prevalence or virulence the amount is raised to 8 or 10 grains per day, then dropping off to 4 or 5. Craig found  $2\frac{1}{2}$  grains of quinin per day sufficient against tertian and quartan infections. James lays stress on giving the daily dose of quinin in the evening.

The particular method of election in giving quinin prophylaxis should be chosen according to the experience of the region. Whatever method of quinin prophylaxis is selected the quinin should be taken throughout the malarial season, say June to November. Those who have had malaria should begin in March or April in order to prevent relapses, for latent malaria is very apt to reassert itself in the spring.

It is advisable not to stop the use of quinin immediately on the advent of cold weather or on leaving a malarial district, even if one has

not had malarial fever. It is good practice to continue the quinin for one or two months, until natural resistance can overcome the infection.

No ill effects have been noted from the prolonged use of quinin as advised above. Carter<sup>19</sup> states that many Americans at Panama, where the malarial season lasts 12 months, took three 2-grain tablets of quinin daily for 2½ years without complaint or injury. The quinin was passed around at the mess tables at Ancon Hospital as regularly as the biscuits.

Occasionally an individual is found who has an idiosyncrasy to quinin. Some people bear quinin less well than others. Five to 7 grains may cause discomfort at first, but a tolerance may be established by persevering a week or two.

Quinin taken as a prophylactic does not develop "blackwater fever"—on the contrary, by diminishing the number and severity of the malarial attacks, it diminishes the liability to hemorrhagic malarial fever. Some persons seem to have an idiosyncrasy to quinin and there is a suspicion that large doses predispose to hemoglobinuria. The etiology and prevention of blackwater fever is still uncertain.

Quinin prophylaxis lowers the malarial sick-rate and death-rate. Celli's statistics for Italy are convincing. Good results are also reported from Greece, Algeria and Panama. The deaths from malaria in Italy during ten years preceding 1902 averaged 14,048 annually, whereas during the nine years following 1902 the average fell to 3,853 per year as a result of quinin prophylaxis. Better results were obtained when quinin prophylaxis was compulsory as in the penal agricultural colony at Castiadas, where the malaria was reduced from 76 per cent. of the force to 5 per cent. The results in the Italian Army were equally good. When the quinin was taken under orders malarial fever fell from 27.5 per cent. in 1902 to 4.9 per cent., of which 3 per cent. were relapses, in 1911. Bass obtained good results in controlling malaria in Bolivar and Sunflower Counties in Mississippi from 1916 to 1918, by using 10 grains of quinin daily before retiring, for a period of eight weeks.

The way quinin prevents the development of malaria is almost certainly by keeping the number of parasites below the number necessary to produce an attack. It does not prevent the development of "carriers," yet it lessens the amount of malaria by diminishing the number of parasites. As malaria lessens, prosperity increases due to improvement in strength and energy of the people, and with increased prosperity comes land better cleared and better drained, houses screened, and better hygiene generally—an endless chain of betterment. It is only in this way—by quinin prophylaxis leading to antimosquito work—that permanent results can be obtained in some places.

<sup>19</sup> P. H. Reports, Mar. 28, 1914. Vol. 29, No. 13, p. 741.

Quinin prophylaxis has advantages that commend it as a prompt, cheap and practical measure. It is at best, however, only tentative and does not take the place of mosquito suppression.

*Quinin treatment* should be aimed at relieving symptoms, preventing relapses and also preventing transmission of the infection to others. The following method of using quinin will usually accomplish all these purposes: For the acute attack, 10 grains of quinin sulphate, by mouth, three times a day for a period of at least 3 or 4 days, to be followed by 10 grains every night before retiring for a period of 8 weeks; for infected persons not having acute symptoms at the time, only the 8 weeks' treatment is required.

### YELLOW FEVER

The prevention of yellow fever rests entirely upon the fact that it is communicated through the bite of an infected mosquito—the *Stegomyia calopus*.<sup>20</sup> The mosquito becomes infected by sucking the blood of yellow fever patients during the first three days of the fever. All the experimental evidence thus far shows that the infection is absent from the blood after the third day, and that mosquitoes do not become infective after this period. The importance of this fact in preventing the spread of the disease is evident. The mosquito, after drinking the infected blood, is not able to transfer the infection to another person until about twelve days<sup>21</sup> have elapsed; that is, it requires about twelve days for the yellow fever parasite, whatever it may be, to undergo its cycle of development in the mosquito. The mosquito once infected remains

<sup>20</sup> This mosquito was first called *Culex fasciatus*, which was changed to *Stegomyia fasciatus*, and then to *Stegomyia calopus*, recently expressed as *Aedes calopus* by Coquillett, and now, *Stegomyia argentens*.

<sup>21</sup> This constitutes the extrinsic period of incubation, in contradistinction to the intrinsic period of incubation, that is, the time between the mosquito bite and the onset of symptoms, which is from 2 to 5 and sometimes 6 days in this disease.

so during the rest of its life, which may be many months. Only the female mosquito transmits the infection; the male *Stegomyia calopus* is a vegetarian; its proboscis is too soft to penetrate the skin. A single sting of a single infected mosquito is sufficient to produce the disease. An infected mosquito may infect more than one person at different times.

The prevention and control of yellow fever are based upon a series of epoch-making investigations and discoveries (1900-1902) by a commission composed of Walter Reed, James Carroll, Aristides Agramonte, and Jesse W. Lazear, medical officers of the United States Army. These experiments have been fully confirmed, and in some respects amplified, by independent workers, namely, Guiteras of Cuba (1901); Ribos of São Paulo (1901); Barreto, de Barros, and Rodrigues, of Brazil (1903); Ross (1902); Parker, Beyer, and Pothier (1903); Rosenau, Parker, Francis, and Beyer (1904); Rosenau and Goldberger (1906), of America; Marchoux, Salimbeni, and Simond (1903); Marchoux and Simond (1906), of France; and Otto and Neumann (1905), of Germany.

Noguchi<sup>22</sup> describes a spirochete (*Leptospira icteroides*), which he isolated from cases of fever at Guayaquil, Lima and Merida, as the cause of yellow fever. It closely resembles *Leptospira icterohaemorrhagiae*, the cause of infectious jaundice.

The virus is "ultramicroscopic," that is, passes the close-grained pores of the finest porcelain filter. While in nature the disease is transmitted only through the bite of an infected *Stegomyia*, the disease may be transferred experimentally by taking some of the blood from a patient during the first three days of the fever and injecting it into a susceptible individual. So far as is known, yellow fever is peculiar to man—no other animal has the disease naturally; Noguchi, however, finds the *Leptospira icteroides* pathogenic for guinea-pigs and rats. At one time it was generally believed that yellow fever infection was conveyed by fomites. This has been disproved, and we now know that there is no danger from soiled clothing or other inanimate things, even though stained with the black vomit and other discharges.

The diagnosis of yellow fever rests upon clinical evidence and is frequently difficult to make, especially in the early stages. It is, therefore, important to screen all cases of fever in a yellow fever campaign until the nature of the illness is established.

**Immunity.**—There is no natural immunity to yellow fever. All persons receiving the infection for the first time seem to be susceptible. Contrary to the usual statement, there is no racial immunity in this disease; negroes, Chinese, Indians, and other races are subject to it. The disease is, however, less severe in negroes than in whites. One attack

<sup>22</sup> *Journ. Exp. Med.*, XXIX, 6, June 1, 1919, and a series of articles in the following numbers.

of yellow fever affords protection against a subsequent attack. The acquired immunity in this disease is one of the strongest known and lasts throughout the lifetime of the individual. Two attacks of yellow fever are almost unknown. I reported a supposed instance in a Spaniard in Havana, but the diagnosis of the first attack was not conclusive.

In endemic areas children often have yellow fever, which leaves them immune for life. The disease often runs a mild and unrecognized course in children, and this fact explains the supposed natural immunity of natives in endemic foci.

Noguchi has prepared a serum for the treatment and a vaccine for the prevention of yellow fever.

**The Yellow Fever Mosquito.** — The yellow fever mosquito has a wide distribution ranging from 38 degrees south to 38 degrees north latitude. They are found in the East and West Indies, China, Sumatra, Java, India, Philippine Islands, Japan, Hawaiian Islands, in the southern part of Italy, Africa, Spain, South America, etc. They usually prefer the lowlands. I have found them as far up the mountains as Orizaba in Mexico, 4,200 feet above sea level. In the United States they are very prevalent south of the Potomac along the gulf coast, but are absent or rare in the higher elevations of Georgia or Alabama, which are, therefore, non-infectable regions.

The yellow fever mosquito is a domestic insect. It breeds by preference in any standing water about the household, such as cisterns, rain barrels, or any collection of water in buckets, bottles, old cans, etc. The yellow fever mosquito does not breed in the fields, woods, and swamps, which are the favorite resorts of the malarial mosquito. The *Stegomyia*

FIG. 23.—*STEGOMYIA CALOPUS* (FEMALE).

mosquitoes do not fly far of their own volition, but show a cat-like tendency to remain about their place of birth or adoption. All these facts have an evident bearing upon preventive measures. A thorough knowledge of the biology of the mosquito is essential to the success of a yellow fever campaign.

It is important to remember that the yellow fever mosquito is chiefly active during the day time. It cannot, however, distinguish between artificial light and sunlight. I have watched *Stegomyia* mosquitoes bite me by electric light at eleven o'clock at night. Its attack is often noiseless and its bite painless. However, as a rule, they rest at night, which,

FIG. 24.—HEAD OF *STEGOMYIA CALOPUS* (MALE).

therefore, diminishes the risk of exposure at that time. The *Stegomyia* mosquito, however, cannot survive for long in the direct rays of a tropical sun. There is, therefore, little danger in visiting a community where yellow fever is epidemic during the day time, provided the person keeps out of houses. The experiences during the last yellow fever epidemic at New Orleans, 1905, showed that the radius of activity of an infected *Stegomyia* is contracted. It may possibly at times fly across the street, but it is evident

that it neither flies far nor is it ordinarily transported to any great distance on railroad cars, although it may be carried over seas on ships.

The yellow fever mosquito may pass a screen composed of 16 strands or 15 meshes to the inch, but cannot pass one containing 20 strands or 19 meshes to the inch. Effective screens must, therefore, be at least this fine.

*Stegomyia calopus* is a grayish mosquito of average size with beautiful glistening silver-white markings. These markings are lyre-shaped on the back of the thorax; silver-white spots are seen on the side of the thorax. White lines are apparent at each tarsal joint and also on the palpi; the scutellum is white. In the female the palpi are much shorter than the proboscis, which at once distinguishes it from *Anopheles*.

*Egg.*—The female lays her eggs on the surface of the water or just above the water line. The eggs do not adhere to one another, and hence do not form the compact boat-shaped mass characteristic of the *Culex*, but float on their sides more or less singly. At the moment of laying

the eggs are a cream color, but rapidly become jet black. They are somewhat cigar-shaped, and measure on the average about 0.55 mm. in length and 0.16 mm. in width at the broadest part. The eggs show marked powers of resistance to unfavorable influences. They may be kept dry for six and one-half months, and still retain their vitality, and hatch out when put back into the water. Freezing does not kill them. The egg probably plays an important rôle in the hibernation of the yellow fever mosquito. The winged insect may also survive a short winter. Under the most favorable conditions as to temperature ( $30^{\circ}$  C.)

FIG. 25.—EGGS OF *STEGOMYIA CALOPUS*.

*Stegomyia* eggs hatch out in about 36 hours after they are laid. Under  $20^{\circ}$  C. they will not hatch at all.

*Larva*.—The egg hatches the larva ("wiggle-tail"), which has a black barrel-shaped respiratory siphon. This distinguishes it from *Culex fatigans*, its common messmate, in which the air tube is brown, longer, and more slender. Although the larva lives in the water, it is strictly an air-breather and must come to the surface for air. It thrusts its breathing tube up into the surface film and remains suspended, head down, at an angle of somewhat less than 45 degrees, which distinguishes it from *Anopheles* larvae, which lie horizontal. A film of oil on the surface of the water is sufficient to obstruct the air tube and thus cause the death of the larva by suffocation. The larva is very timid, so that a slight jar or agitation or a sudden shadow will cause it to wriggle rapidly to the bottom, where, indeed, it may very commonly be observed to feed. The duration of the larval stage is never less than 6 to 7 days, and depends upon the food supply and temperature. Under un-

favorable conditions it may be prolonged for weeks. Freezing for short periods does not appear to injure it.

*Pupa.*—The larva changes into the pupa. The pupa is not provided with a mouth and does not feed. It is an air-breather and spends most of its time at the surface of the water. The pupal stage lasts at least 36 hours, during which time metamorphosis occurs into the imago or perfect winged insect.

*Imago.*—Under the most favorable conditions it is at least 9 days from the time the *Stegomyia* lays its egg to the appearance of the

FIG. 26.—LARVA OF *STEGOMYIA CALOPUS*.  
RESPIRATORY SYPHON OF *CULEX* TO THE RIGHT.

imago. Under natural conditions the length of life of the adult female probably varies greatly. Guiteras succeeded in keeping a presumably infected one alive for 154 days during the fall and winter temperature in Havana. Deprived of water, it does not usually survive longer than  $3\frac{1}{2}$  to 4 days, and only very exceptionally 5 days. This fact has a bearing on the possibility of transporting the mosquito in band-boxes, trunks, and other containers.

**“Aërial” Conveyance.**—It is notorious that yellow fever is usually conveyed but a short distance “aërially”—perhaps across the street, or, more often, to a neighboring house in the rear. This represents a distance of some 75 yards, which is about as far as we may expect it to be thus conveyed, from our knowledge of the habits and flight of the *Stegomyia* mosquito. The longest distance recorded in recent years of aërial conveyance is one of 225 meters (Melier) and one of 456 feet

(Carter). These are entirely exceptional. My experience in the detention of hundreds of susceptible immigrants in quarantine for days in Havana harbor showed that infected *Stegomyia* do not travel a short distance across the water. This observation is in confirmation of others, that vessels moored within 1,200 feet off the shore are entirely safe so far as yellow fever is concerned, provided, of course, personal intercourse is interdicted or supervised.

**Prevention.**—The prevention or suppression of yellow fever may be attacked in either one of its two hosts, man or insect. If every person

FIG. 27.—PUPA OF *STEGOMYIA CALOPUS*.

developing yellow fever were immediately isolated from the *Stegomyia* mosquito, the disease would inevitably cease. The elimination of the *Stegomyia* mosquito would give the same happy result. Usually both methods of attack are employed. It would seem easier to control the human host simply by screening during the first three or four days of the fever. Practically this method has been found insufficient, because the disease is difficult to diagnose in the early stage, and the mild cases escape attention. The essence of yellow fever prevention, therefore, consists in: (1) screening cases of yellow fever and all suspected cases of yellow fever; (2) destruction of infected insects; (3) the suppression of *Stegomyia* through the control of their breeding places. It is a combination of these three methods which was first so brilliantly carried out by Gorgas in Havana in 1901, and later in Panama; by White in New Orleans, 1905; by Liceaga in Vera

Cruz, and recently by Oswaldo Cruz in Rio de Janeiro, in 1909.

Yellow fever patients should be isolated only in the sense of separating them from *Stegomyia calopus*. This may be done by proper screening. It is not necessary to remove the patient to a hospital, although this is desirable, for the reason that a special hospital is more carefully guarded than is practicable in a private house, and the trained assistants are an additional safeguard. As soon as the patient is removed, the mosquitoes in the house and the surrounding houses should at once be destroyed. Yellow fever patients must be moved with caution, for the reason that undue excitement or exertion seems to increase the severity of the disease.

The insecticides best suited for the destruction of mosquitoes are: sulphur dioxid, hydrocyanic acid gas, pyrethrum powder, tobacco smoke, Mim's culicide (camphor and phenol). See page 281. At first glance it might appear to be a hopeless task to attempt to eradicate the yellow fever mosquito in a large city, but that this is possible was demonstrated in New Orleans in 1905, when, after several months of a vigorous campaign, it was difficult to find a *Stegomyia* mosquito. The measures consisted mainly in screening the water cisterns and eliminating all standing collections of water in and about the household. Yellow fever tends to die out in a city with a stationary population; in other words, it burns itself out. An important measure of prevention, therefore, consists in controlling immigration and travel into an endemic center so as to give it a chance to cleanse itself through the elimination of susceptible material.

Maritime quarantine for yellow fever, see page 507.

**References.**—Dr. Charles J. Finlay studied the relation of the mosquito to yellow fever as far back as 1882 and 1883. The first insects used by the United States Army Commission to bring about the demonstration of the new doctrine were received from the hands of Dr. Finlay. Finlay believed that the cause of the disease was a micrococcus and considered that the insects were capable of transmitting the infection a few days after they had stung a yellow fever patient. Sternberg's studies upon yellow fever are published by the Government as a report of the United States Marine Hospital Service on the Etiology and Prevention of Yellow Fever, 1890. Carter's observations at Orwood, Mississippi, upon the extrinsic period of incubation were published in *N. O. Med. and Surg. Jour.*, May, 1900, and the *Medical Record*, June 15, 1901.

The work of the United States Army Commission appeared in the following publications:

"The Etiology of Yellow Fever—a Preliminary Note," Proceedings of the 28th Annual Meeting of the Am. Pub. Health Assn., Oct. 22-26, 1900; also *Philadelphia Med. Jour.*, Oct. 27, 1900.

"The Etiology of Yellow Fever—An Additional Note," *J. A. M. A.*, Feb. 16, 1901.

"Experimental Yellow Fever," *Am. Med. Jour.*, July 6, 1901.

"Etiology of Yellow Fever—Supplemental Note," *Am. Med. Jour.*, Feb. 22, 1902.

A series of articles by Noguchi, describing *Leptospira icteroides*, appeared in the *Journal of Experimental Medicine*, June 1, 1919, Vol. 30, No. 5, and succeeding numbers.

**Prevention of Malaria and Yellow Fever Contrasted.**—For the prevention of malaria the same principles guide us that have been set forth for the prevention of yellow fever. In practical application, however, our methods of attack differ, owing to differences in the habits of the two mosquitoes, and owing to differences in the two diseases. The malarial problem is much more difficult, because it is harder to get rid of *Anopheles* than of *Stegomyia*. The breeding places of the yellow fever mosquito are practically confined to artificial containers in the neighborhood of human habitations, while those of *Anopheles* are found in marshes, pools, or streams, and often in collections of water in the grass or brush. The breeding places of the malarial mosquito cover a much larger area, frequently the whole country, and are rather hard to find and difficult to destroy; also this insect travels much farther from its breeding place than the *Stegomyia*. Compared with yellow fever, the control of the malarial human host presents special difficulties. In yellow fever man is infective to the *Stegomyia* only three days; in malaria the parasites continue in the circulating blood a very long time. In the case of malaria, then, we have to deal with chronic carriers, which, fortunately for us, does not occur in yellow fever. For malaria we have quinin as a prophylactic, whereas no known drug will prevent yellow fever.

### DENGUE

Dengue is an acute specific febrile infection, characterized by pains in the joints and muscles and a variable eruption. It is popularly called *break bone fever* in the south on account of the atrocious character of the pain, and *dandy fever*, from the stiff and dandified gait. It occurs only in tropical and subtropical regions where *Stegomyia* mosquitoes abound.

All who visit the tropics or subtropical countries where dengue prevails are very apt sooner or later to contract this infection. So far as known, few persons have ever died of dengue. Although the mortality is practically nil, the disease is a painful affection and sometimes leaves the body in a weakened condition for long periods of time. In its epidemiology and symptomatology the disease strikingly parallels yellow fever, which adds to its importance. Outbreaks of dengue may precede

and may be coincident with those of yellow fever. In the tropics influenza and dengue are also frequently confused. Dengue also has some resemblance to the three-day fever or pappataci fever of Herzegovina, which is transmitted by the bite of the *Phlebotomus papatassi*, a biting fly. Outbreaks of dengue occur with explosive violence, attacking almost everyone in the community during a brief period. In this respect, the epidemiology of dengue and influenza are strikingly similar. No other disease attacks such a large proportion of the population in a short time.

There is no permanent immunity produced by an attack of dengue. Persons often give a history of an attack in each outbreak. The cause of the disease is not known.

Graham studied dengue in Beirut, Syria, and described a protozoön inhabiting the red blood corpuscles and closely resembling the plasmodium of malaria except for the absence of pigment.<sup>23</sup> Graham believed that this organism undergoes a developmental stage within the mosquito (*Culex fatigans*). He claimed to have observed the spores of this organism "in among the cells of the salivary glands" after 48 hours in mosquitoes which had bitten a dengue patient upon the fourth day of the disease. Graham produced a very severe case of fever resembling dengue by inoculating a man subcutaneously with peptonized normal salt solution containing the salivary glands of a mosquito which had bitten a dengue patient 24 hours before. Graham's observations concerning the parasite in the blood and in the mosquito have not been confirmed, although the subject has been studied by several experienced microscopists. Carpenter and Sutton,<sup>24</sup> however, obtained two positive results out of four experimental cases of mosquito inoculation. The period of incubation in one of these, however, was two weeks, and the subjects were not sufficiently controlled to exclude the bites of other mosquitoes. Agramonte<sup>25</sup> studied an epidemic in Havana which was accompanied by a plague of *Culex fatigans*. He attempted to transmit the disease by mosquitoes, trying various species at various intervals after the insects had fed upon dengue patients, but did not succeed in producing the disease in this way. Guiteras and Finlay<sup>26</sup> endeavored to transmit the disease with *Culex pipiens*, but with negative results. Guiteras, Finlay, Agramonte, and others who have worked upon this subject state that their faith remains unshaken that the mosquito acts as the vector of dengue, despite the negative results of their experiments.

Graham,<sup>27</sup> in 1903, tried a few experiments which seemed to show

<sup>23</sup> *Jour. Trop. Med.*, 1903, Vol. VI, p. 209.

<sup>24</sup> *Jour. A. M. A.*, 1905, XLIV.

<sup>25</sup> *New York Med. Jour.*, 1906, LXXXIV.

<sup>26</sup> *Rev. Méd. Trop.*, 1906, Vol. VII, p. 53.

<sup>27</sup> *Journ. Trop. Med.*, July 1, 1903, Vol. VI, p. 209.

that *Culex fatigans* is able to convey the infection of dengue fever. He admits, however, that in many, perhaps in all, of his experiments, *Stegomyia fasciata* were present amongst his mosquitoes. While he demonstrated that mosquitoes can carry the disease, the variety remained in doubt. Bancroft,<sup>28</sup> in 1905, transmitted dengue in two apparently successful cases which were bitten by *Stegomyia fasciata*, 12 and 10 days after they had bitten dengue patients, but failed when the period was longer. Bancroft worked in an infected district, and his results are not convincing. Ashburn and Craig,<sup>29</sup> in 1907, reported one doubtful case in nine persons bitten by *Culex fatigans*, suggesting the possibility of that species being a vector of dengue. Cleland, Bradley and McDonald,<sup>30</sup> in 1916, reproduced the disease in four out of seven persons on whom biting experiments were conducted with *Stegomyia fasciata* mosquitoes caught in a dengue-infected district in the surroundings of cases of the disease, and some of them known to have fed on a dengue patient on the first and second days of his illness, and then transported to a non-dengue district. The incubation period of the four cases was found to be between five and nine and one-half days. The disease did not spread from any of the above cases. Experiments with *Culex fatigans* were negative. The blood taken from the experimental cases when injected into further persons reproduced the disease.

All our preventive measures are now based upon the supposition that dengue is a mosquito-borne infection. An instance showing the non-contagiousness of dengue is given by Persons, U. S. N.: A squad of marines from the U. S. S. *Baltimore* were given shore leave at Cavite. Twenty of the 24 marines who had been ashore came down with the disease after returning to the ship, while there was a total absence of infection among those who had remained aboard. Observations made at the Naval Hospital at Canacao demonstrated that in the mosquito-free wards the disease did not spread, whereas when the hospital was located at Cavite it was noted that practically every case admitted became infected with dengue while under treatment for the original complaint (Stitt).

### FILARIASIS

The filaria is a long, slender filiform threadworm with a curved or spiral tail. The adult worms live in the connective tissue, lymphatics, and body cavities. The embryos or larvae are found in great numbers in the blood. In several species of which the life history is known mosquitoes act as the intermediate host. The most important filariae of man are: (1) *Filaria bancrofti*, the larva of which is known as *Filaria*

<sup>28</sup> *Austral. Med. Gaz.*, Jan. 1906, p. 17.

<sup>29</sup> *Philippine Journ. Sci.*, II, 2, p. 93, May, 1907; also Craig, *J. A. M. A.*, Vol. 75, 18, p. 1171. Oct. 30, 1920.

<sup>30</sup> *Med. Journ. of Austral.*, Sept. 2, 1916, p. 179; Sept. 9, 1916, p. 200.

*nocturna*, appearing in the blood at night and occurring in all tropical lands, including America; (2) *Filaria loa*, the larva of which is known as *Microfilaria diurna* occurring in the blood by day and prevalent in West Africa and India; (3) the *Microfilaria perstans*, the larva of which is known as *Filaria perstans*, which persists in the blood both day and night, and occurs especially in West Africa and a number of other places. None of these young worms do any appreciable injury in the blood; of the adult worms, only one, namely, *Filaria bancrofti*, can be viewed as serious, causing elephantiasis, dryluria, etc., while the second species, *Filaria loa* is more or less troublesome. According to Manson, we are hardly justified at present in assuming that all the other species are entirely without effect upon their hosts. These parasites infect man throughout the tropical and subtropical belt. In the United States the infection, while not very prevalent, is endemic in Charleston. Francis<sup>31</sup> finds that Charleston, South Carolina, is the only city in the United States showing a considerable number of human infestations. Charleston, it is believed, was infected from a shipload of slaves many years ago.

According to Manson, *Culex fatigans*, and, according to James, the *Anopheles nigerrinus*, are the intermediate hosts. Francis confirms the *Culex fatigans* as the usual host of *Filaria bancrofti*. Development probably takes place in many species of culicines and anophelines. When fed on the blood of a filarial-infested individual, it is found that the filarial larvae soon escape from their sheaths in the thickened blood within the stomach of the mosquito. They pierce the stomach wall, enter the thoracic muscles of the insect, pass through a metamorphosis which takes from 16 to 20 days (longer or shorter, according to atmospheric temperature); they now quit the thorax and a few find their way to the abdomen; the vast majority, however, pass forward through the prothorax and neck, and, entering the head, coil themselves up close to the base of the proboscis and beneath the pharynx and under surface of the cephalic ganglia. This account is taken from Manson, to whose personal interest in this disease we are indebted for the advances in our knowledge of the entire subject of filariasis. The wonderful preparations of Low may be seen at the London School of Tropical Medicine,<sup>32</sup> showing the *Filaria nocturna* in the head and proboscis of the mosquito ready to come out when the proboscis of the insect pierces its victim. The fact that the mosquito is the intermediate host in conveying the infection of *Filaria* rests upon these observations and not upon experiments which demonstrate the actual transference of the disease. Whether the worm may obtain an entrance by any other channel or medium

<sup>31</sup> *Hygienic Laboratory Bull. No. 117, 1919.*

<sup>32</sup> In this country the convincing preparations of Edward Francis are illustrated in *Hyg. Lab. Bull. No. 117, U. S. Public Health Service, June, 1919.*

would, according to Manson, be hard to prove and rash to deny. Our correct preventive measures are based upon the theory that this is an insect-borne disease, although other possible modes of transference must not be neglected. Prophylaxis, therefore, depends upon the suppression of the mosquito and the prevention of the infective mosquito-bite. As it is not definitely known how many species of mosquitoes convey the infection, the preventive measures must be along general lines; a combination of those described under malaria and yellow fever, as well as general sanitation and personal hygiene.

## FLIES

The true flies have but two wings, that is, they belong to the order Diptera. They comprise an enormous number of species. Contrary to popular opinion, flies are poor scavengers. Most flies prefer the sunshine, but species vary greatly in their habits and breeding places. However, surprisingly little is known of the life history and habits of most flies. The subject lacks

attraction—especially the maggots or larval stage. The life history of the house fly in general was, down to 1873, mentioned in only three European works, and few exact facts were given. Dr. A. S. Packard, then of Salem, Mass., studied the house fly and gave descriptions of all its stages, showing that the growth of a generation from the egg to the adult occupies

FIG. 28.—HOUSE FLY (*Musca domestica*), SHOWING PROBOSCIS IN THE ACT OF EATING SUGAR.

from 10 to 14 days. In 1895 Howard further traced the life history and indicated that about 120 eggs are laid by a single female at one time and that a generation is produced every 10 days at the summer temperatures of Washington. There may be, therefore, 12 generations in a summer. If each female lays only 120 eggs (four such batches may be laid) we have the possibility of countless millions coming from a single fly during a single season. Allowing 2,880 flies to the ounce, it has been estimated that the total product of a single fly in 40 days would equal 810 pounds, provided only one-half of them survived; hence, the logical time to begin fly suppression is in the early spring.

Flies transmit disease in one of several ways. The biting flies, such as the tsetse flies, which transmit sleeping sickness, inoculate the trypanosome directly into the system by piercing the skin with their mouth

parts. Biting flies, such as the *Stomoxys calcitrans*, abound in the United States in stables, houses, and also in nature. They have been implicated as go-betweens in anthrax, relapsing fever, horse sickness (Pferdesterbe), and epithelioma of fowls and other infections. Other

FIG. 29.—EGGS OF HOUSE FLY AS LAID IN A MASS.

blood-sucking genera, such as *Tabanus*, *Chrysops*, *Haematobia*, etc., are of common occurrence, but are not known to carry any infection regularly. The common house fly does not bite. These and other non-biting flies transmit diseases by mechanical transfer of bacteria on the surface of their bodies, or by contaminating foodstuffs, etc., with their excreta or vomit.

The following brief account of the common house fly may be taken

FIG. 30.—EGGS OF HOUSE FLY. Some have hatched.

as a type of the life history and habits of flies in general. Remedies and preventive measures depend upon the peculiarities in the life history and habits of each particular genus and species.

**Life History of the *Musca Domestica*.**—The eggs of the common house fly are usually laid in masses (Fig. 29) in certain favorable spots, each mass being the result of deposition by several females. In 6 to 8 hours the eggs hatch into larvae (maggots), which grow rapidly and are fully developed in 4 or 5 days. Each larva then becomes a pupa in a

FIG. 31.—LARVAE OF HOUSE FLY.

hard brown case—the puparium. In 5 days more the pupal case opens and the adult fly appears for a season of activity covering several weeks. It takes about 10 days from egg to imago. Most of them die in the early autumn, in great part due to a fungus disease, caused by *Empusa muscae* which becomes prevalent among the flies at this season of the year. Those remaining out of doors are killed by the first cold nights, those which find their way into heated buildings gradually die out, and there is no evidence that hibernation of adult flies occurs. They overwinter as larvae or pupae in manure heaps or beneath the soil. It is possible for flies to continue breeding throughout the winter in heated locations such as animal houses and the like, where food and breeding materials are present.

FIG. 32.—PUPARIUM OF HOUSE FLY.

The chief breeding place of common house flies is in horse manure. They also have been found to breed in human excrement, fermenting vegetable and putrefying animal matter, in the bedding in poultry pens, in refuse hog hair, in tallow vats, in carcasses of various animals, and in

garbage and organic material of all kinds: All of which means that if we allow the accumulation of filth we will have house flies.

The larvae of house flies have a tendency to crawl away from their breeding places; many of them burrow into the loose ground just beneath the manure piles, or crawl under boards or stones, or into dry manure

FIG. 33.—STABLE FLY (*Stomoxys calcitrans*). After Brues.

collected under platforms or the like. This tendency of migrating appears three or four days before pupating. The larvae leave the moist manure for a dry, dark place. This migrating habit is of great advantage to the winged fly, at the time of emergence, as it affords an easy path to freedom. Advantage may be taken of this migrating habit to trap many larvae. They can be made to leave the manure if it is kept moist, and can be trapped and drowned in a box or tray partly filled with water.

FIG. 34.—HEAD SHOWING PROBOSCIS (*Stomoxys calcitrans*). After Brues.

**Life History of *Stomoxys Calcitrans*.**—*Stomoxys calcitrans*, the biting stable fly, is very similar to the house fly in its life history and in appearance during the preparatory stages, but develops more slowly, requiring nearly a month to undergo a complete life cycle. The eggs are laid like those of the house fly in horse manure, but more frequently in fermenting heaps of grass, cow-dung, brewer's refuse ("spent hops"), etc.

The adult flies are much like the house fly, but have a sharp, needle-like proboscis. They feed exclusively on mammalian blood and are a great annoyance to horses and cattle in late summer and autumn. They bite persons less frequently, but are of importance on account of their possible relation to transmitting infections. The stable fly can best be controlled by eliminating its breeding places.

**Flies as Mechanical Carriers of Infection.**—Leidy in 1864 attributed the spread of gangrene in hospitals during the Civil War to the agency of the house fly. Shortly thereafter it was discovered that the bite of the gad-fly may transmit anthrax from cattle to man. Later it was found that purulent ophthalmia of the Egyptians is carried by the house fly, and the spread of an infectious conjunctivitis known as "pink eye" in the South has been shown by Hubbard to be facilitated by little midges of the genus *Hippelates*. Reference has already been made to the bite of the tsetse flies in spreading nagana, sleeping sickness, and other trypanosomatic infections. Recently the stable fly has been shown to be able to transmit various infections in a mechanical way.

It is now known that typhoid fever and other intestinal infections may be transmitted by the common house fly. Celli in 1888 fed flies with pure cultures of typhoid, tuberculosis and anthrax, and showed that the virulent bacilli were passed in the dejecta. Kober in 1892 was one of

FIG. 35.—WING OF STABLE FLY (*Stomoxys calcitrans*).

the first to call special attention to the danger of contaminating food supplies by flies coming from the excreta of typhoid patients. The United States Army Commission—Reed, Vaughan, and Shakespeare<sup>33</sup>—studied the presence of typhoid fever in our camps during the Spanish-American War in the summer of 1898. They concluded that flies undoubtedly serve as carriers of the infection. "Flies swarm over infected fecal matter in the pits and then deposit it and feed upon the food prepared for the soldiers at the mess tents. In some instances, where lime had recently been sprinkled over the contents of the pits, flies with their feet whitened with lime were seen walking over the food."<sup>34</sup> Vaughan subsequently stated that he considered that about 15 per cent. of the cases of typhoid in the camps were caused by fly transmission.

Alice Hamilton<sup>35</sup> isolated typhoid bacilli from 5 out of 18 house flies captured in Chicago in the privies and fence near a sick room during a local water-borne outbreak. It has been shown experimentally that living

<sup>33</sup> Rep. on Origin and Spread of Typhoid Fever in U. S. Military Camps in Spanish War of 1898, 1904.

<sup>34</sup> *Am. Journ. Med. Sci.*, 1899, CXVIII, 10.

<sup>35</sup> *Jour. A. M. A.*, 1903, XL, 40, p. 576.

typhoid bacilli may remain in or upon the bodies of flies a long time.

Ficker<sup>36</sup> isolated *B. typhosus* from flies from a house in which there were 8 cases of typhoid fever. He further proved by experimentation that flies fed on typhoid bacilli transmitted the microorganism 23 days after feeding. Klein,<sup>37</sup> Faichnie,<sup>38</sup> Graham Smith,<sup>39</sup> Bertarelli,<sup>40</sup> and others also isolated *B. typhosus* from flies kept in nature, but in proximity to the infection. Howard studied fly abundance in relation to the origin and prevalence of typhoid fever in the District of Columbia in the summer of 1908.<sup>41</sup> No particular correlation between the prevalence of the flies and the prevalence of the disease could be made out.

FIG. 36.—THE "LITTLE HOUSE FLY" (*Homalomyia canicularis* ♂. After Hewitt.

Flies undoubtedly spread the infection of typhoid fever, but the importance of the rôle they play in this regard varies considerably with circumstances. In camps, unsewered towns, and overcrowded places in poor sanitary condition the danger from flies may be considerable, but even under the worst conditions it is doubtful

whether flies ever play the major rôle or are responsible for the bulk of typhoid fever, as has been stated. In a well-sewered city, such as Washington, we concluded that the flies are probably responsible but for an occasional case of the disease. It is very difficult in any particular instance to know quantitatively just how much of the infection is conveyed by flies and how much by contacts. The danger of flies is great enough without the need of exaggeration, and their suppression fully justifies the best energies of the health officer. It is perhaps a mistake to call the common house fly the "typhoid fly," not alone for the reason that the disease is spread in many other ways, but for the reason that the fly is responsible for the spread of many infections other than typhoid fever. Flies undoubtedly play the same rôle in dysentery, cholera, and all other intestinal infections that they do in typhoid fever. Tizzoni and Cattani in 1896 demonstrated active cholera organisms in the dejecta of flies caught in the cholera colonies of Bologna, Italy. These

observations were subsequently verified and extended by Simonds, Offelman, McRae, and others.

It is quite evident that flies lighting upon a case of smallpox, measles, scarlet fever, and other exanthematous disease may very readily transmit these infections to another person. I have actually seen maggots breeding in the open lesions of a case of smallpox treated in huts at Eagle Pass, Texas.

Flies may, in the same mechanical way, transmit the infection of crysipelas, anthrax, glanders, and other skin infections. It is known that flies may ingest tuberculous sputum and excrete tubercle bacilli which may remain virulent as long as 15 days. Flies have also been associated with leprosy and many other diseases.

FIG. 37.—WING OF HOUSE FLY, SHOWING HOW IT CARRIES DUST PARTICLES.

Esten and Mason<sup>42</sup> counted the bacterial population of 415 flies and found that the number of bacteria on a single fly may range all the way from 550 to 6,600,000. Early in the fly season the numbers of bacteria on flies are comparatively small, while later the numbers are very large. The places where flies live also determine largely the number of bacteria they carry. The average of the 415 flies was about one and one-quarter million bacteria. The method of the experiment was to introduce the flies into a sterile bottle and pour into the bottle a known quantity of sterilized water, then shake the bottle to wash the bacteria from the body of the fly. The numbers, therefore, only represent those carried on the outside and not those in the intestinal tract. The experiments of Esten and Mason were designed to simulate the number of microorganisms that would come from a fly in falling into milk.

Torrey<sup>43</sup> found that a single fly may carry from 570 to 4,400,000 bacteria upon its surface, and from 16,000 to 28,000,000 in its intestinal tract. The prevailing types are *Streptococcus equinus fecalis* and *salivarius*, which are also found in the breeding and feeding places of

<sup>42</sup>Storr's *Agricultural Experiment Station. Bull. No. 51*, April, 1908.

<sup>43</sup>J. A. M. A., May 11, 1912, LVIII, No. 19, p. 1445.

the house fly. Torrey also obtained three cultures of *B. paratyphosus* which is especially significant.

Even though flies breed in manure, and the larvae teem with bacteria, the adult winged insect, when newly hatched, contains fewer micro-organisms. This cleansing is due to the active phagocytosis which takes place during metamorphosis from pupa to imago. The bacteria in the intestinal tract of the newly hatched imago are mostly extruded soon after emergence from the puparium.

Bacot,<sup>44</sup> however, has shown that certain species of bacilli ingested during the larval period of *Musca domestica* can retain their existence while their host is undergoing the process of metamorphosis, and continue their existence in the gut of the adult fly, but that their number diminishes suddenly after emergence. In a subsequent work Bacot<sup>45</sup> demonstrated that *Bacillus pyocyaneus* may thus survive. Faichnie<sup>46</sup> shows how *B. typhosus* may also persist. Ledingham confirms these conclusions, and states that he has recently isolated *B. typhosus* from pupa, the larvae of which have fed on this organism.

Graham-Smith<sup>47</sup> recovered *B. anthracis* from blow flies bred from larvae fed on meat infected with the organism, but failed to recover *B. typhosus* and *B. enteritidis*.

Among the list of diseases of which there is more or less evidence that the infection may be conveyed by flies are: typhoid, cholera, dysentery, diarrhea in infants, anthrax, yaws, erysipelas, ophthalmia, diphtheria, smallpox, plague, tropical sore, parasitic worms, sleeping sickness, loa loa, relapsing fever, deer fly fever, and several infections of the lower animals.

An interesting light was thrown on the possible modes of dissemination of the eggs and larvae of hookworms by Galli-Valerio (1905). He placed eggs and larvae of *Ankylostoma duodenalis* in a bottle with flies, and on washing found many eggs and encapsulated larvae which had adhered to their bodies, but none in the flies' intestines.

Flies may transmit the virus of disease mechanically, either through their dejecta or upon their mouth parts, legs, and other surfaces of the body. The flies may carry the infection directly to our lips or indirectly to our food or to any surface upon which they light.

English observers prove that house flies may come a mile from an infected dump to the nearest village. Hodge,<sup>48</sup> investigating the abundance of flies on the cribs in Lake Erie off Cleveland, came to the conclusion that flies are blown at least six miles offshore, and that they gather on the cribs as temporary resting places.

<sup>47</sup> *Repts. to Local Gov. Bd.*, New Series, No. 53, 1911.

<sup>48</sup> Hodge, C. F.: *Science*, 1913, XXXVIII, 512.

The maximum flight in the experiments made at Cambridge, England, was 770 yards across open fenland.<sup>49</sup> Their dispersal is favored by fine weather and warm temperature. They will even go against or across the wind, attracted perhaps by the odors it may convey. Flies do not travel as far in towns as in open country, probably on account of food and shelter afforded by the houses.

**Suppression.**—The suppression of the common house fly may be accomplished by striking at their breeding places. In a city this does not present very great difficulty. It resolves itself simply into a matter of cleanliness—organic cleanliness of our environment. The chief breeding places are in horse manure and garbage. These should be given first attention. One neglected stable will furnish a plague of flies for an entire neighborhood. Their suppression in a well ordered city fortunately is neither expensive nor difficult, but it requires a well-trained and capable corps of inspectors with sufficient authority to enforce the regulations. The suppression of flies by voluntary effort through the slow process of education cannot be relied upon.

In cities, stable manure should be placed in properly covered receptacles and removed at least once a week. This one measure obviates the use of kerosene, chlorid of lime, Paris green, or arsenate of lead, all of which are expensive and uncertain unless used frequently and in liberal amounts; further, they may decrease the fertilizing value of manure.

Garbage should be kept in water-tight cans with good covers and removed frequently, especially in the warm weather. Refuse on city lots, in back yards, in alleys, about wharves, markets, and similar places should be regularly taken away. Householders, provision merchants, storekeepers, and others should be held responsible for the cleanliness and tidiness of their premises, and those who violate these simple and primitive hygienic requirements should have their places cleaned up for them at their own expense.

Where it is not practicable to remove manure, it may be kept covered in a dark place, which discourages the visitation and breeding of

FIG. 38.—THE HODGE FLY TRAP ON A GARBAGE CAN.

<sup>49</sup> Local Gov. Board on Public Health Subjects, 1913, N. S. No. 85, pp. 20-41, by Hindley and Merriman, also *Jour. Hyg.*, 1914, XIV, 23.

flies, and in addition should be carefully screened. Larvae may be destroyed. The best results are obtained by the use of borax (sodium borate) and calcined colemanite (crude calcium borate).<sup>50</sup> Both substances possess a marked larvicidal action, but appear to exert no permanent injury on bacteria. In order to kill fly eggs and maggots, apply 0.62 pound borax or 0.75 pound calcined colemanite to every 10 cu. ft. (8 bushels) of manure immediately on its removal from the barn. Apply the borax particularly around the outer edges of the pile with a flour sieve or any fine sieve and sprinkle two or three gallons of water over the borax treated mass. As the maggots congregate at the outer edges of the pile, most of the borax should be applied there. The treatment should be repeated with each addition of fresh manure. Borax may also be applied to floors and crevices in barns, markets, stables, etc., as well as to street sweepings. The borax does not appear to injure the fertilizing value of the manure if it is applied carefully, applied so as in no case to exceed 0.62 pound per 10 cubic feet.

Unsatisfactory results are obtained with the use of kerosene, iron sulphate, potassium cyanid, copper sulphate, lime sulphur mixture, Paris green, sodium fluorite, formaldehyd, and the Isthmian Canal Commission larvicide.

Another method of suppression which has been found quite effective in certain army camps is the simultaneous application of three measures: first, the removal of the manure as early in the morning as possible, before it has become infested; second, the removal of the manure to a considerable distance and building it up as a compact heap in which the pressure and heat tend to prevent breeding, except possibly at the outer edges, but even these will soon become unfavorable in very dry weather; third, the use of fly traps kept well baited. Fly traps work most efficiently when there is no manure, kitchen refuse or other soil pollution to compete with the bait as an attraction.

Flies are thirsty insects and will be attracted to a saucer of water containing a little formalin (1.25 to 2.5 per cent.). Sodium salicylate (1 per cent.) is a muscicide of about equal efficiency.<sup>51</sup> This simple measure will kill many of them in a room. The salts of barium, cobalt, and other poisons, such as arsenic, potassium bichromate, or quassia infusion, may be used instead of formalin, and are better bait if sweetened. Sticky fly-paper,<sup>52</sup> fly traps, electric fans, and other well-known measures will help dispose of a certain number of flies, but all these measures are tentative, and attack the problem at the wrong end.

The fly has a number of natural enemies: various fungi, especially one belonging to the *Entomophthorae*, which destroys flies in the au-

<sup>50</sup> The United States Department of Agriculture (*Bull. of the U. S. Dept. Agriculture*, No. 118, July 14, 1914).

<sup>51</sup> *Hyg. Lab. Bull. No. 108.*

<sup>52</sup> Formula for sticky fly-paper, see page 272.

tunn. Flies also harbor protozoa and nematodes as parasites, which, however, seem to do them little harm. The little bright red objects often seen attached to flies are mites, which are usually only temporary ectoparasites stealing a free ride. When spider webs are not disturbed they catch, and the spiders devour, a large number of flies. The house centipede (*Scutigera*) also sometimes catches and eats flies, as do the common garden toad, some lizards, and a few insectivorous birds.

Flies and similar dipterous insects are responsible for the transmission of a large number of diseases, most of which are discussed elsewhere. It now remains to consider sleeping sickness, transmitted by the tsetse fly (*Glossina palpalis*), pappataci fever, transmitted by a biting dipterous insect (*Phlebotomus papatasi*), and deer fly fever (*Crysops*). For convenience a general consideration of the trypanosomes is inserted in this chapter.

### SLEEPING SICKNESS

#### (*The Trypanosome Fevers—Trypanosomiasis*)

Sleeping sickness was limited to tropical Africa, especially in the Congo, on the shores of Victoria Nyanza, and about the head waters of the Nile, but is gradually spreading. Many thousands have perished from this infection, caused by *Trypanosoma gambiense* and transmitted by the tsetse fly (*Glossina palpalis*). The disease is characterized by two stages: in the first there are irregular fever, glandular enlargements, an erythematous rash, and localized edemas. In the second there are slowly increasing lethargy and other morbid, nervous symptoms. After a chronic course sleeping sickness usually terminates in death; few cases recover. Many instances of fatal "homesickness" in the negroes during the slave trade are now believed to have been this disease.

The *Trypanosoma gambiense* was discovered by Dutton in 1901 during the first or febrile stage of sleeping sickness, and subsequently studied by Dutton and Todd, who did not at first suspect the relation of the trypanosome to sleeping sickness. This was shown by Castellani in 1903. The trypanosomes are found in the cerebrospinal fluid, in the enlarged lymphatic glands, and also in the circulating blood. It seems that when the trypanosomes are inoculated through the skin by the tsetse fly they are temporarily blocked by the lymphatic glands. From here small numbers of them pass into the circulation and thus to other parts of the body. They are always in the fluids; never in the cells or tissues. Novy and McNeal in 1903 accomplished the remarkable feat of growing trypanosomes in the water of condensation of blood agar tubes. Pure cultures show marked differences between the *Trypanosoma lewisi* of the rat and the *Trypanosoma grussei* of horses and

other domestic animals. So far no one has succeeded in cultivating the *Trypanosoma gambiense* in artificial culture media.

Sleeping sickness in Rhodesia is caused by *Trypanosoma rhodesiense* (Stephens and Fantham, 1910), transmitted by *Glossina morsitans* (Kinghorn and York, 1912). The disease in Rhodesia is similar to that in the Gambia; furthermore, the parasites and tsetse flies of both are closely allied species.

The relation of the tsetse fly to the transmission of this disease rests upon satisfactory evidence. Dutton and Todd, as well as others, find these flies abundant wherever sleeping sickness exists. Wherever

FIG. 39.—TSETSE FLY (*Glossina palpalis*).

the *Glossina palpalis* is absent sleeping sickness never spreads, as Koch observed; while, on the other hand, if a case is brought to a locality where the tsetse fly prevails, it soon spreads. It is probable that the transmission by the tsetse fly is not of the simple mechanical type, but that the parasite undergoes a sexual evolution within the insect. Flies seem to lose their power of transmission soon after feeding on an infected animal, and Bruce considers it thoroughly impossible that mechanical transmission alone could explain the situation. Kleine's experiment on monkeys, confirmed by Bruce, showed that the flies may convey the disease 21 days after one feeding upon a monkey infected with sleeping sickness. In another experiment by Taute, which is reported by Kleine, infection was produced on each of the first three days after feeding. From the fourth to the tenth day no infection resulted. The flies then became infective again and produced the disease from the eleventh to the forty-fourth day. Kleine<sup>53</sup> concludes that the period of development or extrinsic period of incubation in the fly is about 20 days or a little less. Flies remain infective at least 75 days. Not all flies which

<sup>53</sup> Bull. of the Sleeping Sickness Bureau, No. 7, 1909.

drink blood containing trypanosomes become infective. The proportion is about 1 in 20. Of the flies caught in nature in endemic areas, from 2 to 10 in one thousand are capable of transmitting the disease to animals. Novy has emphasized, and Minchin has corroborated the fact, that tsetse flies may harbor non-pathogenic as well as pathogenic trypanosomes, a fact which impairs the value of a great deal of the microscopic work which has been done. As a means of avoiding the accident of dealing with naturally infected flies, it is best to use those which have been bred and raised in the laboratory.

**Prevention.**—The prevention of sleeping sickness in the present state of our knowledge depends first upon isolation of the sick, protecting both the sick and the well against fly bites, and the suppression of the flies themselves. The sick should be isolated in a location where *Glossina palpalis* is absent, or in a well-screened and carefully managed hospital. It is especially important to isolate all those who carry the infection in the early stages of the disease, whether they feel sick or not. It is not sufficient simply to isolate those who have enlarged glands but careful blood examinations must be made. The trypanosomes have been found in the circulating blood of persons with normal lymph glands.

All persons taken to the hospital and detention station are given a thorough treatment with atoxyl (a combination of arsenious acid and anilin oil). Atoxyl is one-tenth as toxic and contains about three times as much arsenic as arsenious acid alone. The dose is from  $\frac{3}{4}$  to 3 grains (0.05-0.2 grams) subcutaneously, combined with antimony in the form of tartar emetic.

The extermination of the tsetse fly seems a hopeless task. The larvae remain in the body of the mother fly until fully developed and are then dropped on moist soil, in which they burrow to undergo transformation to the adult state; therefore, clearing of the land in limited locations largely diminishes the number of flies. Clearing the brush exposes the earth to the sun, and the surface becomes dry and hard, so that flies die during the pupal period. This measure has limited possibilities, but is useful, as Shirata points out, around ports, in the neighborhood of villages, wharves, and other places.

The tsetse fly may also be fought by suppressing its food supply. It must obtain the blood of some vertebrate animal every two or three days. The German Commission has shown that on the banks of the Victoria Nyanza the tsetse fly lives largely upon crocodile blood. This fact was discovered by the interesting observation that the flies frequently contain parasites peculiar to the crocodile's blood. Koch believes that the disease may be successfully controlled by destruction of the crocodiles, a theory which later research has rendered very unlikely, for the flies feed upon other animals.

THE IMPORTANT TRYPANOSOMES—(Modified from Nacht and Mayer)

Zoological Name	First Described by	Name of the Disease	Animals Infected in Nature	Geographical Distribution	Transmitted by
<i>Tr. lewisi</i> (Kent, 1880)	Chaussat, 1850 Lewis, 1878	Generally produces no noticeable symptoms	Rats, <i>Mus rattus decumanus</i> , <i>rudecens</i>	Apparently everywhere these rats occur	Rat fleas (according to Rabinowitsch and Kempner) <i>Haematopinus spinulosus</i> (Burmeister) according to v. Prowazek
<i>Tr. theileri</i> (Laveran, Bruce, 1902) <i>Tr. evansi</i> (Steel, 1885)	Theiler, 1902 Evans, 1880	Gall sickness Surra	Cattle Horses, cattle, camels, dogs and other mammals	South Africa (Transvaal, Orange Cape), India, Indo China, Philippines, Mauritius, North Africa	<i>Hippobosca rufipes</i> (?) <i>Tabanus tropicus</i> and <i>lineola</i> (?) <i>Stomoxys calcitrans</i> and <i>nigra</i> (?)
<i>Tr. brucei</i> (Plimmer & Bradford, 1889)	Bruce, 1894	Nagana	Most mammals, especially domestic animals	Greater part of Africa	<i>Glossina morsitans</i> and <i>fuscus</i> <i>Glossina pallidipes</i> (?)
<i>Tr. conigerdum</i> (Doflein, 1901)	Rouget, 1894 Schneider & Bufard, 1899	Dourine	Horses	Europe (Spain, Hungary, South Russia), south coast of Mediterranean, North Africa, Asia Minor, Persia, N. America, Chile (?)	Transmitted by coitus <i>Haematopinus spinulosus</i>
<i>Tr. equinum</i> (Voges, 1901)	Elmassian, 1901	Mal de Cadéras	Horses	South America (Argentina, Bolivia, Brazil, Uruguay, Paraguay)	<i>Musca brava</i> ; <i>Stomoxys calcitrans</i> and <i>nebulosa</i> (?)

<i>Tr. dimorphon</i> (Dutton & Todd, 1904)	Dutton and Todd, 1904		Horses	Senegambia	<i>Glossina palpalis</i> (?) <i>Stomoxys</i> (?)
<i>Schizotrypanum cruzi</i>	Aragao, 1910	Barbiero fever	Man	South America	<i>Conorhinus megistus</i>

Authorities advocate the extermination of big game on the belief that they are the vertebrate reservoir of the parasite. This, however, requires further study before attempting to put such a radical measure into effect.

Todd and Wolbach<sup>54</sup> suggest a systematic examination of the natives in the endemic area by gland palpation and gland puncture. The latter consists in withdrawing a drop of fluid from one of the enlarged lymphatic glands by means of a hypodermic syringe. The little drop of bloody fluid thus obtained is examined as a fresh preparation under the microscope for trypanosomes. By this method these investigators found at least 0.8 per cent. of the population of the Gambia to harbor trypanosomes. If all the infected individuals could be collected in villages for observation, treatment, and isolation, it would do much to limit the disease.

*Chagas' Disease*, or Brazilian trypanosomiasis, is caused by *Trypanosoma cruzi*, and transmitted by *Lanus magistus* (*Triatoma magista*), a predacious bug which has acquired a liking for human blood.

Trypanosomes are the cause of numerous diseases in animals, as will be seen by reference to the table on page 320. So far as known, sleeping sickness and Chagas' Disease are the only important diseases of man produced by trypanosomes. Kala-azar, however, is produced by a flagellated protozoön parasite which is closely allied to the trypanosomes.

Practically all animals are susceptible to almost all trypanosomes. The trypanosomes which infect man may readily be transmitted to monkeys, guinea-pigs, rabbits, etc.

### DEER-FLY FEVER

#### (Pahvent Valley Plague)

Deer-fly fever is a mild specific febrile infection due to *Bacterium tularense*, and transmitted by Crysops, a biting fly. The disease is limited to the rural population of Millard County, Utah. It is characterized by enlargement of the lymph glands, which drain the bitten area, and by a fever of septic type lasting from three to six weeks. The site of the bite and the affected lymph glands become tender, inflamed and commonly suppurate. There is marked prostration and the patient is confined to his bed. Probably two dozen cases occurred in the Pahvent Valley in Utah in each of the years 1917, 1918 and 1919. The disease is mild; the first case known to have terminated fatally was reported in 1919.

*Bacterium tularense* was discovered by McCoy and Chapin<sup>55</sup> in 1912

<sup>54</sup> *Annals of Tropical Medicine and Parasitology*, Vol. V, No. 2, Aug., 1911, p. 245.

<sup>55</sup> *Public Health Bull. No. 53*, U. S. Public Health Service.

as the cause of a plague-like disease of rodents in California. The year before, McCoy<sup>56</sup> described this new plague-like disease which he found in the ground squirrels of California. *Bacterium tularense* grows only on coagulated egg yolk. It is a small coccobacillus, and is doubtless identical with the organism described by Francis<sup>57</sup> as the cause of deer-fly fever in Utah. Wherry and Lamb<sup>58</sup> described an infection of man with this organism.

Francis has shown that guinea-pigs and rabbits are susceptible when inoculated with blood or with pus from a suppurating gland of a patient. The disease in experimental animals is fatal; the lesions are caseation of the lymph glands and small necrotic foci throughout the liver and spleen. The infection presumably is kept alive in Utah in rabbits and perhaps other rodents.

### PAPPATACI FEVER

(*Three-day Fever, Phlebotomus Fever, Sand-fly Fever*)

Doerr and Russ,<sup>59</sup> and also Doerr, Franz, and Taussig originally described a three-day fever which occurs on the shores of the Mediterranean; it is also known in India, Egypt and South America. The cause of pappataci fever, or sand-fly fever, is not known. The period of incubation is 3 to 5 days; the onset is sudden. Uncomplicated cases are never fatal. The disease occurs in epidemics with a high incidence rate. Pappataci fever has many resemblances to dengue fever. It is transmitted through the bite of a dipterous insect—*Phlebotomus papatasi*. This little gnat only bites in darkness and only in houses. Prevention consists in using a fine mosquito netting, and insecticidal agents.

### FLEAS

Fleas are laterally flattened, wingless creatures related to the Diptera. They pass through a complete metamorphosis: egg, larva, pupa, and imago. The adult female flea deposits her eggs among the hair or fur of the host animal, but, unlike the eggs of many ectoparasites, they are not fastened to the hairs and therefore fall freely to the ground. The eggs are oval, whitish, and smooth and about half a millimeter long. The larvae escape from the eggs in 2 to 5 days. They are able to break the egg shell by a slender process on the top of the head which disappears after the first molt. The larva is a slender, legless, cylindrical creature,

<sup>56</sup> *Public Health Bull. No. 43*, U. S. Public Health Service.

<sup>57</sup> *Public Health Rpts.*, U. S. Public Health Service, Sept. 12, 1919.

<sup>58</sup> *Jour. Inf. Dis.*, 1914, Vol. 15, p. 331.

<sup>59</sup> *Schiffs und Tropen Hyg.*, 1909, Vol. XIII, No. 22, p. 693.

whitish or yellowish in color, with a head and 13 segments. There are a few scattered hairs or bristles on the body, and at the tip is a pair of corneous processes. At the front of the head is a pair of biting jaws or mandibles. The larvae feed on almost any kind of refuse. They have been reared on the sweepings from rooms. There is always some organic matter in such dust, and this is doubtless their nourishment. In houses the larvae usually crawl into cracks or in carpets, where they feed and grow. Those that infest wild animals probably feed on the refuse in the nests or retreats of these animals. It will be noticed that, unlike the mosquito, the larval and pupal stages of the flea are not aquatic. They remain in the larval stage from a week to ten days,

FIG. 40.—THE INDIAN RAT FLEA (*Xenopsylla cheopis* Rothsc.)<sup>60</sup>

sometimes two weeks, molting the skin three times in this interval. Then they spin flat, white, silken cocoons in which they transform to the pupal stage. In from 5 to 8 days the adult flea emerges from the cocoon. The period of their transformation is affected by the temperature and moisture. In warm, damp weather a generation may develop in 10 days or 2 weeks, but usually about 18 days to 3 weeks elapse from the egg to the adult. Although some moisture is necessary for their development, an excess is apt to destroy the larvae.

The leaping ability of adult fleas is familiar to all. This, however, has been greatly exaggerated. The British Plague Commission determined that fleas jump 3 to 5 inches, never over 6. No part of the leg is particularly enlarged, so that the jump is made by the entire leg, as in the leaf-hopper insect, and not by the femur of the hind leg, as in the grass-hopper. Fleas do not vary much in size. They are mostly about 2 to 3 millimeters long. The adult insect has a hard, strongly chitinized body. The mouth parts resemble somewhat those of the mosquito. Both the male and the female flea are capable of piercing the skin

<sup>60</sup> Formerly *Loemopsylla cheopis*.

to obtain blood and thus transmit infection. Fleas, as a rule, prefer certain hosts, but are not as particular in this regard as are many parasites. Those species which are best known are found to attack several hosts, including man. This is one reason that makes them dangerous so far as plague and other infections are concerned. Over 300 species

FIG. 41.—THE COMMON RAT FLEA OF EUROPE AND NORTH AMERICA (*Ceratophyllus fasciatus* Bosc.).

are described. Formerly all fleas were classified in the single family Pulicidae, genus *Pulex*; now they are arranged in many genera and these genera grouped into families.<sup>61</sup> *Pulex serraticeps* or *Ctenocephalus canis* occurs all over the world, infesting cats and dogs, also many other animals. They are frequently brought into houses upon domestic animals, and thus become troublesome to man. *Pulex irritans* is the

FIG. 42.—THE HUMAN FLEA (*Pulex irritans* Linn.).

human flea, sometimes called the "house flea" or "common flea." The fleas concerned in the transmission of plague are *Xenopsylla cheopis*, the India rat flea, and *Ceratophyllus fasciatus*, the common rat flea of Europe and North America. Plague may also be transmitted by *Cteno-*

<sup>61</sup> Banks: "The Rat and Its Relation to the Public Health," P. H. and M. H. S., p. 69.

*cephalus felis*, the cat flea; *Pulex irritans*, the human flea; *Ceratophyllus acutus*, the squirrel flea, and doubtless other genera and species.

In addition fleas act as intermediate hosts for certain tapeworms (*Dipylidium caninum*), and doubtless are the mechanical or biological carriers of other infections. Nicolle incriminates the flea in typhus fever.

**Pulicides.**—Adult fleas succumb to the agents applicable to insects in general. Mitzmain<sup>62</sup> has shown that water is of little value in the destruction of mature fleas. Glycerin is also practically inert as a pulicide, but tincture of green soap is very quick and effective. Kerosene (coal oil) is a very efficient flea destroyer. An emulsion of petroleum and soft soap, with or without naphthalene, is a good pulicide. Formalin, phenol, mercuric bichlorid, and tricresol in the strength used as disinfectants are of little value in killing fleas. Powdered sulphur seems to be of no value.

Hydrocyanic acid is the most efficient of the gases because it kills both the fleas and their eggs. The amount used is 2½ ounces of sodium cyanid per thousand cubic feet of air space. See page 515. Sulphur dioxid, 3 pounds per thousand cubic feet, and also disulphid of carbon will kill fleas, but cannot be depended upon to destroy their eggs. Chloroform or ether first anesthetizes fleas, and if continued kills them. This is important for the safe handling of rats, squirrels, and other plague animals. The host may be chloroformed and the fleas and other ectoparasites removed with a comb. The anesthetic may be controlled by practice so that the host will recover and the fleas die, or both recover, or both die, as may be desired.

In flea-infected houses the larvae, living in the cracks of the floor, etc., may be controlled by sprinkling a thin coating of flake naphthalene on the floor and then leaving the room tightly closed over night. In the morning the naphthalene may be swept up and what remains used again.

Kitasato<sup>63</sup> confirms the efficacy of the method of collecting rat fleas by turning guinea-pigs loose in a building. The fleas collect upon the guinea-pigs and both the fleas and the pigs may then be examined for plague bacilli.

## RELATION OF PLAGUE TO RATS AND FLEAS

Plague is primarily a disease of the rat and secondarily of man. This fact is now firmly established not only by the recent experiences, but especially through the admirable studies of the Indian Plague Com-

<sup>62</sup> *Public Health Reports*, July 29, 1910, Vol. XXV, No. 30, p. 1039.

<sup>63</sup> Kitasato, S.: "Bubonic Plague and Rat Fleas." *Berl. klin. Wchnschr.*, Oct. 13, L, 41, pp. 1881-1928.

mission,<sup>64</sup> which established beyond doubt the fact that plague may be and generally is transmitted from rat to rat and from rat to man through the agency of the flea—*Xenopsylla cheopis*—and sometimes by *Ceratophyllus fasciatus*, et al. During some plague epidemics it has been noted that the rats die in great numbers before and during the outbreak. It is now known that this epizootic in the rat is true plague. In nature, rats suffer both with acute and chronic plague.

In the laboratory, rats may be infected with plague by ingestion, by application of the virus to mucous or cutaneous surfaces, or by subcutaneous inoculation. In nature, rats may become infected by any of these means, but probably flea transmission is the only one that ordinarily operates to any extent.

Rats are great travelers, and have carried the plague to all quarters of the globe. A more complete discussion of the rat and its relation to plague and other diseases will be found on page 335.

Within the past few years it has been discovered that, while the rat is the great medium for the spread of plague, the disease was probably preserved from extinction in Thibet by another rodent, the marmot (*Arctomys bobac*). The tarbagan, a fur-bearing rodent, infected trappers and traders, who in turn started the epidemic of pneumonic plague in Manchuria in 1910-1911. In California the infection has gotten into the ground squirrels (*Citellus beecheyi*), in which the disease will doubtless be kept alive for many years to come. To realize the full importance of these discoveries, it is only necessary to call to mind that, in order to eradicate plague a warfare against the rat alone is not sufficient, but must include the rodents mentioned and perhaps others.

Simond in 1897 advanced the theory that plague was carried by fleas. This theory was developed by J. Ashburton Thompson and others and conclusively proved by the Indian Plague Commission. The exact method by which the flea transmits the infection from animal to animal is not definitely understood. The mouth parts appear not to remain infected. It is improbable that the salivary secretions contain the microorganisms. It is known that the plague bacilli may live in the digestive tract and be passed in live and virulent numbers in the dejecta. It is easy to understand how some of the infected dejecta may be rubbed or scratched into the little wound produced by the flea bite.

Bacot and Martin<sup>65</sup> found that *Xenopsylla cheopis* and *Ceratophyllus fasciatus* may transmit plague during the act of sucking by regurgitating some of the blood. These investigators found that in a proportion of infected fleas the plague bacilli develop to such an extent in the esophagus and proventriculus as to occlude the alimentary canal at the entrance to the stomach. Fleas in this condition are not prevented from sucking

<sup>64</sup> *Journal of Hygiene*, Vol. VI, No. 4; Vol. VII, Nos. 3, 6; Vol. VIII, No. 2.

<sup>65</sup> *Ibid.*, Plague Supplement, III, p. 423, 1914.

blood as the pump is in the pharynx, but they only succeed in distending an already obstructed esophagus, and on cessation of the pumping act some of the blood is forced back into the wound. Such fleas are persistent in their endeavors to feed, and this renders them particularly dangerous.

When it was found that the common rat flea of Europe, the *Ceratophyllus fasciatus*, does not readily bite man, considerable doubt was thrown upon the part played by the flea in plague transmission. These negative results, however, are offset by the convincing positive proofs of the British Plague Commission in India, and by McCoy and Mitzmain in San Francisco, who showed that under certain conditions the rat flea will bite man, especially if the natural food supply is limited,

FIG. 43.—A SQUIRREL FLEA (*Hoplopsyllus anomalus* Baker.).

and that these fleas may feed on a man's hand even in the presence of a rat.

Raybaud <sup>66</sup> calls attention to the fact that the rat flea (*Ceratophyllus fasciatus*) is able to hibernate for a month or 45 days without nourishment, and that virulent plague germs may persist unharmed in its stomach during this length of time and even longer. This fact may be of importance for the transmission of plague to a distance.

Bacot and Martin <sup>67</sup> found that infected fleas which were fed regularly might live for 50 days, at from 10 to 15° C. and 23 days at 27° C. and remain infected at death.

The Commission for the Investigation of the Plague in India <sup>68</sup> found that infection conveyed by fleas might take place three weeks after the flea population had any opportunity of imbibing infected blood. Bacot <sup>69</sup> has observed that fleas (*Ceratophyllus fasciatus*) are able to carry the

<sup>66</sup> *Presse Médicale*, March 8, 1911, No. 20.

<sup>67</sup> *Jour. A. M. A.*, Apr. 10, 1915, LXIV, 15, p. 1251.

<sup>68</sup> Reports on Plague Investigations in India, *Jour. Hyg.*, 1906, VI, 435.

<sup>69</sup> Observations on the length of time that fleas (*Ceratophyllus fasciatus*) carrying *Bacillus pestis* in their alimentary canals are able to survive and retain the power to reinfect with plague, *Jour. Hyg.*, Plague Supplement IV, 1915, 770.

bacillus of plague for periods up to 47 days and subsequently infect a mouse.

The indications thus are, that plague infection may persist in fleas at least 1 or 2 months in cold weather and subsequently give rise to an epizootic.

The development of plague bacilli in the flea, as well as the activity of the flea itself, is restricted both in very hot and very cold weather. Extremes of temperature are therefore not favorable for the spread of the bubonic form of the disease. The pneumonic form spreads best when the weather is very cold.

It should be remembered that, according to the observations of Nuttall and Yersin, flies and possibly other insects may also occasionally convey the infection. Walker<sup>70</sup> considers, as the result of experiments, that bedbugs and other biting insects play an important rôle in the transmission of plague. Bacot<sup>71</sup> has demonstrated that bedbugs are capable of carrying *Bacillus pestis* and may thus infect mice after a period of 48 days' starvation.

### RATS AND OTHER RODENTS

Rats, mice, squirrels, and other rodents have become a serious problem in preventive medicine, and their habits and methods of suppression may be considered conveniently at this place. Plague being primarily a disease of rats, the prevention and suppression of this infection resolve themselves into a war upon these rodents. For the control of plague it is, therefore, necessary to have a knowledge of the life history and methods of attacking the problem in the lower animals. In addition to plague, rats are a reservoir of trichinosis. They are responsible for infectious jaundice, for the transmission of certain tapeworms and other parasites. They are subject to leprosy, cancer, and numerous other diseases, some of which concern man. Rats and mice also are carriers of *B. enteritidis*, which is connected with food infection.

Rodents comprise more than one-third of all living species of mammals, and exceed any other mammalian order in the number of individuals. They have no canine teeth, but strongly developed incisors. Only the front of the incisors is covered with enamel, which keeps them sharp and chisel-like, owing to the more rapid wearing away of the softer dentine. The incisor teeth continue to grow throughout the life of the animal. The most extensive family of rodents is the *Muridae*, which includes the true rats and mice, typified by the genus *Mus*.

<sup>70</sup> Walker: *Indian Med. Gaz.*, 1910, No. 3, p. 93.

<sup>71</sup> Notes on the Development of *Bacillus pestis* in Bugs (*Cimex Lectularius*) and Their Power to Convey Infection, *Jour. Hyg.*, Plague Supplement IV, 1915, p. 779.

Trouessart, in his "Catalogus mammalium," enumerates 250 species of *Mus* described before 1905. Since that date a number of new forms have been described.

The genus *Mus* is characterized by narrow, ungrooved incisors; three small-rooted molars; soft fur mixed with hairs, sometimes with spines; a rudimentary pollex (thumb) having a short nail instead of a claw; a long tail bearing rings or overlapping scales and often naked or nearly so. The ears are rather large, the eyes bright and prominent, and the muzzle somewhat pointed.

The distinction between rats and mice is arbitrary and based on size. Of the many species of the genus *Mus* only three or four have developed the ability to adapt themselves to such a variety of conditions as to become cosmopolitan. Four have found lodgment in America:

The common house mouse, *Mus musculus*.

The English black rat, *Mus rattus*.

The Egyptian or roof rat, *Mus alexandrinus*.

The brown rat, *Mus norvegicus* (formerly *decumanus*).

The black rat and the roof rat differ from each other mostly in color, and some zoölogists regard them as races of the same species. The brown rat is also known as the gray rat, barn rat, wharf rat, sewer rat, and Norway rat.

The black rat (*Mus rattus*) has been known in Europe since the twelfth century, and from there has been carried to America. The brown rat (*Mus norvegicus*) came later, and, as it is more destructive, larger, and more ferocious, it is rapidly driving the black rat before it. The brown rat differs somewhat in habits from the black rat, especially in that it burrows, which protects it against its enemies and renders its suppression more difficult.

The house mouse holds its own everywhere against the brown or Norway rat, as it is able to get into holes too small for the rat to follow. Albinism and melanism occur in all species; pied forms are common. The white rat of the laboratory is an albino form of either *Mus rattus* or *Mus norvegicus*.

**Breeding and Prevalence.**—The brown rat is more prolific than either the roof rat or the black rat. The brown rat reproduces from three to five times a year, each time bringing forth from 6 to 9, and sometimes as many as 22 or 23, young. They breed more rapidly in temperate and equable climates than in those of great variability. The number of rats is only limited by the food supply and opportunities to nest. Few people have any conception of the enormous numbers of rats in cities and on farms. Although few are seen in the day time, at night they fairly swarm along river fronts and wharves, as

well as in sewers, stables, warehouses, markets, and other places where food may be found. A few instances will illustrate the prolific habits and give an idea of the destructive tendency of rats.

In 1901 an estate near Chichester, England, was badly infested with rats;<sup>72</sup> 31,981 were killed by traps, poisons, and ferrets, while it is estimated that tenants, at the threshing, destroyed fully 5,000 more. Even then the property was by no means free from rats.

During the plague of rats on the island of Jamaica, in 1833, the number killed on a single plantation in a year was 38,000.<sup>73</sup> The injury to sugar cane on the island caused by the animals was at that time estimated at half a million dollars a year.

The report of the Indian Famine Commission in 1881 affords one of the best illustrations of the number of rats that may infest a country. An extraordinary number of the animals at that time inhabited the Southern Deccan and Mahratta districts of India.<sup>74</sup> The autumn crop of 1878 and the spring crop of 1879 were both below the average, and a large portion of each was destroyed by rats. The resulting scarcity of food led to the payment of rewards for the destruction of the pests, and over 12,000,000 were killed.

The average life of a rat is about two years.

**Migration.**—The migrations of rats have often been recorded. The brown rat is known in Europe quite generally as the migratory rat; the Germans call it the *Wanderratte*. Pallas relates that in the autumn of 1772 they arrived from the East at Astrakhan, southeastern Russia, in such great numbers and so suddenly that nothing could be done to oppose them. They crossed the Volga in immense troops. The cause of this general migration was attributed to an earthquake, but, since similar movements of the same species often occur without earthquakes, it is probable that only the food supply of the animals was involved in the migration which first brought the brown rat to Europe.

Seasonable movements of rats from houses and barns to the open fields take place in the spring, when green and succulent plant food is ready for them. The return movement takes place in the autumn. This seasonal migration is notable even in large cities. In 1903 a multitude of migrating rats spread over several counties of western Illinois. They traveled in great armies and invaded the farms and villages of Rock Island and Mercer counties, and caused heavy losses during the winter and summer of 1904. In one month Mr. Montgomery of Mercer county killed 3,435 rats on his farm. He caught most of them in traps.

In England a general movement of rats inland from the coast oc-

<sup>72</sup> *The Field*, London, Vol. C, p. 545, 1902.

<sup>73</sup> *New England Farmer*, Vol. XII, p. 315, 1834.

<sup>74</sup> *British Med. Jour.*, Sept. 16, 1905, p. 623.

curs every October. This is known to be closely connected with the closing of the herring season. During the fishing the rodents swarm to the coast attracted by the offal left in cleaning the herring, and when this food fails the animals troop back to the farms and villages.

An invasion of rats (*Mus rattus*) in the Bermuda Islands occurred about the year 1615. Within two years they had increased so alarmingly that none of the islands was free from them. The rodents "devoured everything that came in their way—fruits, plants, and even trees"—so that for a year or two the people were nearly destitute of food. A law was passed requiring every man in the island to keep 12 traps. In spite of all efforts the animals continued to increase; but they finally disappeared, so suddenly that it is supposed they must have been victims of a pestilence.

While stationed upon Angel Island in San Francisco harbor I observed several migrations of rats between the army post and the quarantine station, which were about a mile apart and separated by an intervening ridge. Everyone is familiar with the sudden invasion of stores, factories, and other structures with these rodent pests, which causes considerable economic loss.

**On Vessels.**—Rats are found on all vessels; they are great travelers. It is through this seagoing tendency that the rat has become cosmopolitan. Rats get on board vessels readily as they lie at their dock; sometimes they are carried on board in the cargo.

It is very important to prevent the introduction of rats on vessels at plague-infected ports; it is also important to prevent the passage of rats from ship to shore, particularly if the vessel is from a plague port. In order to accomplish this, it is necessary to exercise particular care. In extreme cases the ship should not approach the dock, but the cargo should be handled by means of lighters. When the ship lies at its moorings in a stream or in the open bay, rats may get on board by swimming, and climbing in through the hawse pipe. Rats rarely swim more than one-quarter to one-third of a mile. If the vessel ties up at the dock, inverted funnels should be placed on the hawsers. The gang-planks should be watched during the day and always taken up at night. Vessels from plague ports should always be treated with sulphur dioxide, preferably when empty, and always before leaving, and also en route, to kill the rats that may be on board. A wise measure in international sanitation would be to require all vessels, whether trading at plague ports or not, to fumigate for rats no less than three or four times a year. For destruction of rats on vessels, see page 505.

**Food.**—Rats are not strictly herbivorous, as might be inferred from their dentition; they are practically omnivorous. Their bill of fare includes grains and seeds of every kind; flour, meal, and all food products

made from them; garden vegetables, mushrooms, bark of growing trees, bulbs, roots, stems, leaves, and flowers of herbaceous plants; eggs, chickens, ducklings, squabs, and young rabbits, milk, butter, and cheese; fresh meat and carrion; fish, frogs, mollusks, and crustaceans; they are also cannibals. This great variety of food explains the ease with which rats maintain themselves in almost any environment.

**Habits.**—The roof rat (*Mus alexandrinus*) and the black rat (*Mus rattus*) are more expert climbers than the brown rat, which is larger and clumsier. In buildings the brown rat keeps mainly to the cellar and lower parts, where it commonly lives in burrows. From these retreats it makes nightly excursions in search of food. The roof rat and the black rat live in the walls or in the space between ceilings and roofs. Rats readily climb trees to obtain fruit. In the tropics the roof rat and the black rat habitually nest in trees. In the open, rats seem to have defective vision; by daylight they move slowly and uncertainly; on the contrary, at the side of the room and in contact with the wall they run with great celerity. This fact suggests that the *vibrissae* (whiskers) serve as feelers, and that the sense of touch in them is extremely delicate. The animals always prefer narrow places as highways—another circumstance which may be made use of in placing traps.

The ferocity of rats has been grossly exaggerated. They fight fiercely when cornered. They sometimes bite sleeping infants and adults. Ordinarily the probability of being bitten by rats is remote, and the bite is not usually poisonous. Miyake<sup>75</sup> has described a "rat-bite disease," called in Japan Sodoku, or rat-bite fever.

**Rat-Bite Fever.**—Rat-bite fever is<sup>76</sup> a rare and curious infection sometimes following a rat bite. In all only 80 cases of human infection have been reported in the literature up to 1918. The symptoms come on after the wound has healed. There is inflammation of the bitten part with swelling of the lymph glands, paroxysms of fever of the relapsing type which may last a very long time, and an eruption of the skin which usually occurs during the second febrile paroxysm. The case fatality is about 10 per cent.

The cause of rat-bite fever is probably a spirochete described by Japanese investigators—*Spirochaeta morsus muris*.<sup>77</sup> This spirochete is found in the blood of rats and also in human cases. It is not found in the saliva of infected rats and the infection is supposed to be transmitted during the bite by blood caused by wounds of the gums. Bearing upon a spirochete as the cause of this infection, salvarsan seems

<sup>75</sup> *Mitt. a. d. Grenzgeb. d. Med. u. Chir.*, 1902; also Proescher, *Internat. Clinics*, IV, 25th Series, p. 77.

<sup>76</sup> *Journ. Exp. Medicine*, Vol. XXIII, No. 1, January 1, 1916, p. 39.

<sup>77</sup> *Ibid.*, 1916, XXIII, p. 249; 1917, XXV, No. 1, p. 33; 1917, XXV, No. 1, p. 45; 1919, XXXI, No. 4, p. 366.

to be specific in the experimental disease in animals; favorable results are reported for man.

Other infections may follow rat bites. Thus, Schottmuller in 1914 described *Streptothrix muris rattii*. The same or a similar streptothrix was also found by Blake in a fatal case at the Peter Bent Brigham Hospital in Boston, by Ruth Tunnickliff in Chicago, and by Tileston in New Haven. *Acute infectious jaundice*, due to the *Spirochaeta icterohemorrhagiae*, is an infection of rats transmitted to man. The disease occurs in outbreaks, especially among troops, and is discussed on page 335.

**Plague in Rats.**—It is now known that rat fleas are responsible for most cases of human plague of the bubonic type, and in addition are the most frequent medium by which plague is carried from one locality to another. They also convey the plague infection to other rodents, such as ground squirrels.

The clinical manifestations of plague in rats are not very evident. It is generally said that a plague-infected rat staggers about with a drunken gait, loses fear of its natural enemies, and is readily captured. Rats experimentally infected show no marked manifestations of illness until shortly before death, when they become quiet, crouch in the corner of the cage, and try to hide. It is rather surprising that comparatively few dead plague rats are found in endemic centers. In the San Francisco campaign McCoy estimates that certainly not more than 20 per cent. of the infected rodents were found dead, the remainder being trapped.

Rats suffer both with acute plague and chronic plague, the lesions of which differ.

The diagnosis of plague in rats may be made macroscopically. The Indian Plague Commission, which had the opportunity of examining an enormous number of plague rats in Bombay and elsewhere in India, state that "the results of tests carried out for the purpose of comparison make it manifest that the naked eye is markedly superior to the microscopic method as an aid in diagnosis, and as the result of our experience we are prepared to make a diagnosis of plague on the strength of the macroscopical appearance alone, even though the other results of cutaneous inoculation and culture are negative and the animals show signs of putrefaction." The experience of McCoy and others in the Federal Plague Laboratory in San Francisco leads to the same conclusion. It should be remembered, however, that occasionally plague occurs in rats without gross lesions. This has been observed by Dunbar and Kister and also by McCoy. In any critical case the bacteriological confirmation is essential.

Acute plague in rats is characterized by engorgement of the subcutaneous blood vessels and a diffuse pink color of the subcutaneous structures and muscles. The diagnosis may often be inferred at the

first incision. The lymphatic glands of the neck, axilla, groin, or pelvis are enlarged and frequently surrounded by a hemorrhagic exudate and edema. The liver is granular with focal necroses, the spleen enlarged and friable, and pleural effusions are common.

Chronic plague in rats has been encountered in a considerable number of cases among *Mus rattus* in the Punjab villages of Kasel and Dhand. It has not been found in California. In the chronic disease the lesions consist of purulent or caseous foci, usually of the visceral type; that is, they occur as splenic nodules and abscesses, or mesenteric abscesses. Sometimes the abscesses are situated in the regions of the peripheral lymph glands. Plague bacilli are either absent or very scanty upon microscopic examination in these abscesses, but they may be recovered by cultural methods or more surely by inoculating the material into susceptible animals. There is no evidence to show that chronic rat plague has anything to do with the recurrence of acute plague among the rats.

Rats may be infected by the ingestion of infective material or the application of virulent plague bacilli to a mucous or cutaneous surface, or by subcutaneous injection of the microörganism. The infection may also be transferred from rat to rat through the agency of the flea. In nature the mode of transference probably takes place through all of these methods, but commonly through the flea.

Contrary to the general impression, the wild rat has a considerable resistance to plague infection. The Indian Plague Commission found that 59 per cent. were immune when inoculated by the subcutaneous method from the spleen of infected rats. A series of experiments conducted in the Federal laboratory in San Francisco also showed a high grade of immunity, especially among the large rats. About 15 per cent. of small rats and about 50 per cent. of large rats were found to be immune when inoculated with highly virulent material. The experiments demonstrated that this immunity is not acquired through a prior attack of the disease, but must be a natural immunity.

The natural subsidence of plague among rats in any community is a point about which much more evidence must be obtained before we can speak with any degree of authority. It may be due to a lack of susceptible material, possibly to a loss of virulence of the organism, but it seems more probable that it is due to a change in the number or activities of the rat fleas.

In a rat survey to determine the existence of plague the number of rats examined should be at least 1,000 for every 10,000 of the human population, and a preliminary survey should be made in order that the most promising locations shall be trapped.

## RAT-BORNE DISEASES

ACUTE INFECTIOUS JAUNDICE <sup>77a</sup>

(Epidemic Catarrhal Jaundice—Weil's Disease.)

Infectious jaundice, or epidemic catarrhal jaundice, has been known for a long time to occur among troops, among sewer workers, among miners, and among agricultural laborers working in wet soil, as rice planters; also people who handle food, at least in Japan, are said to be attacked with especial frequency. It was recognized as a clinical entity by Ozenam, 1849; Monneret, 1859; Laverau, 1865; Lancerau, 1882; Landouzy, 1882; Mathieu, 1886; and Weil, 1886, who described four cases with typical symptoms; the disease is very often called by his name.

It is an acute infection, caused by the *Spirochaeta icterohaemorrhagiae*, and characterized by malaise, prostration and gastro-intestinal symptoms at the onset; by fever of varying degree, and by jaundice of varying intensity and duration. In severe cases bleeding from mucous surfaces and albuminuria are common. Light cases are clinically indistinguishable from ordinary catarrhal jaundice.

In most outbreaks the mortality is low, but in Japan the infection is both more prevalent and more virulent than in Europe or America. Among the Japanese the case fatality rate is as high as 38 per cent., while in European soldiers in the Great War it did not exceed 2 or 3 per cent. The infection is endemic on all continents among rats. The disease in man is associated with moist soil and moderate temperature; that is, few cases occur in the hottest or coldest weather. Sporadic cases are recorded, but usually the disease occurs in epidemic form, often with a high attack incidence.

The cause of acute infectious jaundice is the *Spirochaeta icterohaemorrhagiae* of Inada,<sup>78</sup> (1916) and his co-workers. Noguchi<sup>79</sup> believes the spirochete belongs to a special genus and has named it *Leptospira icterohaemorrhagiae*.

An account of an outbreak of jaundice among troops in the War of 1812 has come down to us. Not less than 71,691 cases occurred among white troops of the Union Army in the American Civil War. In the South African War 5,648 cases of epidemic jaundice occurred among the British troops. Many cases of acute infectious jaundice occurred among the troops on both sides of the Rhine in the World War. It prevailed from Belgium to Gallipoli.

<sup>77a</sup> A complete bibliography to date is contained in Neil's article on "The Problem of Acute Infectious Jaundice in the United States," *U. S. Public Health Reports*, Reprint No. 466, May 10, 1918.

<sup>78</sup> *Journ. Exp. Med.*, XXIII, 377, Mar., 1916.

<sup>79</sup> *Ibid.*, XXV, 755, May, 1917.

Official statistics give no adequate idea of the prevalence of this disease, as large numbers of men continued on duty throughout their illness. Regimental medical officers have stated that as many as one-tenth of their men actually in the trenches were jaundiced. In one battalion there were 100 cases during October, but only 36 were regarded as of sufficient severity to be sent into a field ambulance. It was called trench jaundice. A number of epidemics of catarrhal jaundice have been reported among the civil population of the United States. A list of these outbreaks is given by Neil.<sup>80</sup>

**The Relation of the Disease to the Rat.**—Acute infectious jaundice is a disease primarily of rats, secondarily of man. About 10 per cent. or more of all wild rats, wherever examined, harbor the spirochetes. Rats have a remarkable immunity to the infection, gained perhaps through long association between parasite and host. The spirochetes live in the kidneys of the rats and are excreted in the urine. They have also been found in the blood and other organs, and in the mouth.

Noguchi found the spirochetes in rats caught about the Bronx; Jobling and Eggstein found 10 per cent. of the rats examined in Nashville to be infected; Neil 10 per cent. of the rats in Washington; and Otteraaen found the parasites in the rats of Chicago. This, therefore, reveals a latent danger to which we have been constantly exposed, but from which we can escape as long as sanitary conditions are satisfactory.

The credit of first finding the *Spirochaeta icterohaemorrhagiae* in rodents belongs to the Japanese investigators who first demonstrated these parasites in the kidneys of field mice. Further investigations in the coal mining regions of Japan showed that 40 per cent. of the wild rats harbored the organism, and that many cases of infectious jaundice in human beings occur in this region.

**Transmission.**—Just how the disease is usually transmitted from rat to rat and from rat to man is not entirely clear. There are several possibilities. There is scant evidence that the infection is transmitted from man to man.

The spirochete is found in the kidney of the rat and is excreted in the urine which contaminates the soil, and infection takes place either through the skin or by the mouth. Susceptible animals may be infected by either route. The infection will pass through the unbroken skin of guinea-pigs. The spirochete is frail,<sup>81</sup> but may live three days in moist soil; it soon dies when dried. This probably explains the relation of the infection to moist soil and a moderate temperature. It also makes clear the reason why the wet trenches, overrun with rats, favored the transfer of the disease from rats to man during the World War.

<sup>80</sup> U. S. Public Health Reports, May 10, 1918.

<sup>81</sup> Journ. Exp. Med., May 1, 1918, p. 609.

The spirochete has been found in the mouth of rats and the infection has been transmitted to guinea-pigs by the bites of such rats. This probably is not the usual method of spread in nature.

Foulerton<sup>82</sup> found *Spirochaeta icterohaemorrhagiae* in the feces of infected guinea-pigs, and its presence in the feces of cases of spirochetel jaundice in man may be assumed.

There is no adequate evidence that any insect plays a part in the transmission of the disease, although the experimental evidence in this regard is by no means complete.

*Prevention* consists in warfare against rats (page 338). The disease is not known to be communicated directly from man to man. Sanitation both in civil and military life to guard against contamination with rat excrement is an essential element of prophylaxis. Shoes should be worn, especially in wet soil and where the infection abounds. Food must be carefully guarded against rats and mice, for infection by the mouth occurs, and food soiled with rat urine is hazardous. The heat of cooking is sufficient to kill the spirochete. Prophylaxis against this disease is a question of biologic cleanliness.

### RAT LEPROSY

An infection resembling leprosy occurs spontaneously among rats and bears a close resemblance to the disease in man, but it seems that rat leprosy is not communicable to man. For a further discussion of rat leprosy see page 414.

### TRICHINOSIS

The three most important hosts for the *Trichinella spiralis* are man, swine, and rats. The infection is spread by one animal eating the flesh of another. It is, therefore, evident that if the disease occurred only in hogs and man it could be controlled. Hence, a well-directed public health campaign against trichinosis should consider the eradication of rats, especially around slaughter houses, butcher shops, hog pens, and similar places.

Trichinosis is very common among rats; they become infected by eating each other, by eating scraps of pork found on the offal pile of slaughter houses, butcher shops, or in swill. Swine become infected by eating rats and infected offal. Man becomes infected almost exclusively by eating pork or boar meat that has not been thoroughly cooked. See page 830.

*Food infection* due to the Gaertner group of bacilli may be associated with rats and mice, for these rodents may be carriers of these micro-organisms. The opportunity for food to become contaminated with rat and mice feces is frequent in the slaughter house and butcher shop, in

<sup>82</sup> *Jour. Pathol. and Bacteriol.*, Vol. XXIII, No. 78, October, 1919.

the grocery and home, and in storage and transportation. See page 704.

**Other Parasites.**—Rats and mice may harbor eleven species of internal parasites which also occur in man. Several of these are of academic importance only.

Those which concern us principally, in addition to *Trichinella spiralis*, are *Hymenolepis nana*, *Hymenolepis diminuta*, and *Labdium intestinalis*. Rats are also susceptible to experimental infection with *Trypanosoma gambiense*, the cause of sleeping sickness, but are not known to play any part in the spread of this disease under natural conditions.

Lynch<sup>83</sup> states that the rat (*Mus norvegicus*) suffers from spontaneous amebic dysentery similar to that occurring in man. The rat is, therefore, a possible disseminator of dysentery amebas pathogenic for man.

Rats have also been accused of dragging typhoid from the sewers to our food. The connection is close and the possibility apparent. A recent outbreak of typhoid fever in an asylum has, in fact, been traced to this source by Dr. Mills.<sup>84</sup>

### ECONOMIC IMPORTANCE

The destruction of food, merchandise, and property by rats is so great that this alone would justify active measures of suppression, even though they were not responsible for plague, trichinosis, and other infections. Rats destroy grain while growing; invade stores, destroy flowers, laces, silks, carpets; eat fruits, vegetables, meat, etc., in the market; destroy by pollution ten times as much as they eat; cause conflagration by dragging matches into their holes; gnaw lead pipes and floors of houses; ruin artificial ponds and embankments by burrowing; destroy eggs and young poultry; damage foundations, floors, doors, piers; in short, they have become the worst mammalian pest among us. It is estimated that in the United States alone the losses due to rat depredations are over \$167,000,000 annually computing the upkeep of a rat at one-half cent a day.<sup>85</sup>

### SUPPRESSION OF RATS

The extermination of the rat is hopeless; they are very intelligent and cautious. Extermination seems a biological impossibility, for killing off large numbers gives the survivors an easier living. Millions of rats have been killed in India, Japan, San Francisco, and other places during the recent plague measures without making

<sup>83</sup> *Jour. A. M. A.*, LXV, No. 26, Dec. 25, 1915, p. 2232.

<sup>84</sup> *Brit. Med. Jour.*, January 21, 1911.

<sup>85</sup> *Public Health Bull.* No. 103, June, 1919.

an appreciable impress upon the numbers remaining. They may be exterminated and kept out of a limited area, such as a ship, a granary, a stable, a warehouse, a market, or local compound. In the well-built residential sections of a city, with concrete walks, asphalt streets, stone cellars, and few stables, there are very few rats. In ten years of residence in such a district in Washington I never saw or heard of one in the neighborhood. *Mus rattus* and *Mus alexandrinus* are much more difficult to suppress than *Mus norvegicus*; indeed it is probable that we have no very satisfactory method of dealing with these rats, owing to the fact that frequently they live in trees and in the fields.

The measures for the repression and destruction of rats will be considered under: (1) rat-proof buildings, (2) keeping food from rats, (3) natural enemies, (4) traps, (5) poisons, (6) domestic animals, (7) shooting, (8) fumigation, and (9) bacterial viruses.

**Rat-proof Buildings.**—This is a measure of first importance in the fight against rats. Rats can only gain entrance to a cement structure properly constructed through neglect or ignorance. They come in through drain pipes if left open; through doors, especially from alleys; and through basement windows. Once in, they intrench themselves in out-of-the-way places, nest behind rubbish, and are difficult to dislodge. The lower parts of the outer doors of public structures, such as markets and wharves, should be reinforced with metal to keep the rats from gnawing through. Basement windows should be screened and doors provided with springs to keep them closed. Screens or wire cloth to keep out the rats must be not less than 20 gauge nor greater than  $\frac{1}{2}$  an inch mesh. The special points of ingress and egress of rats which must be guarded against besides basement windows and doors are hatches, ventilators, skylights, unused chimney flues, and openings around water, sewer, gas, and steam pipes, and electric wires.

Foundation walls should be laid without a break around the entire building and should extend not less than 18 inches beneath the surface of the surrounding soil, and should always be flush with the under-surface of the floor above. Floor joists should be imbedded in this wall or the spaces between the joists filled in and completely closed up to the floor level. Ground areas should be concreted with a layer at least 3 inches in thickness, finished with a wearing surface of cement about  $\frac{1}{2}$  an inch thick. The walls of a wooden house should have one foot of concrete between the sheathing and lathing. All water and drain pipes should be surrounded with cement where they pierce the walls. Rat holes may be closed with a mixture of cement, sand, and broken glass, or sharp bits of crockery and stone.

Buildings may be raised from the surface of the ground on piers, thus rendering them rat-proof. Cribs for grain in the country can be so raised and further protected with metal netting.

Aside from dwellings, the chief refuges for rats in cities are sewers, wharves, stables, provision houses, markets, out-buildings, slaughter houses, restaurant kitchens, bakery shops, candy factories, and uninhabited structures. Modern sewers are highways and not nesting places for rats. They find a safe retreat from nearly all enemies under wooden sidewalks. In the country it is important to build corn cribs, barns, and granaries rat-proof with the liberal use of cement, iron sheeting, or galvanized iron netting.

**Keeping Food from Rats.**—Well-fed rats mature quickly, breed often, and have large litters. A scarcity of food helps all other suppressive measures. Garbage and offal must be disposed of so that rats cannot get at such stuff. Well-covered garbage cans should be required and the garbage frequently removed and burned. To deposit it upon the ground anywhere only invites and nourishes rats and other vermin. Slaughter houses are centers of rat propagation. The offal is best disposed of by burning. Care should also be taken as to the disposal of remnants of lunches in office buildings and the disposal of organic waste generally. Produce in provision stores may be protected with wire cages.

**Natural Enemies.**—The natural enemies of the rat are the larger hawks, owls, snakes, skunks, foxes, coyotes, weasels, minks, dogs, cats, and ferrets. The persistent killing off of the carnivorous birds and mammals that prey upon rats has been an important factor in the increase of these rodents in the United States. Rats actually destroy more eggs, chickens, and game than all the wild animals combined.

**Traps.**—There are many kinds of traps, such as the guillotine, spring trap, the cage trap, the barrel and pit trap. One of the best is the old-fashioned wire cage trap. The rats get in but cannot get out. In placing the trap it is advisable to leave a rat in as a decoy. The trap should be placed along runways, or the entrance to the trap may be arranged so that the rats first have to go through a pipe, as they like to explore dark passages. It requires ingenuity to trap rats successfully. They are very wary and avoid man-smell. To guard against this the traps may be burned and then smeared with the bait, always handling them with tongs or properly prepared gloves. Cheese, bacon, grain, and also meat, vegetables, or bread are the best baits.

**Poisons.**—Poisons are objectionable in dwellings, owing to the odor of the dead rats. They are of service in granaries, stables, wharves, storage depots, garbage dumps and similar places where rat-proofing is difficult or too expensive. Most rat poisons are dangerous to children as well as to chickens and other domestic animals, and, therefore, the greatest care must be exercised in their use. It requires experience in laying out poisons; the old rats are very smart and will refuse the bait unless artfully concealed and judiciously placed.

The principal poisons used for rats are barium carbonate, strychnin,

arsenic, and phosphorus. In several states the law requires that notice of intention to lay poison must be given to persons living in the neighborhood. Poisons for rats should never be placed in open or unsheltered places. In buildings and yards occupied by poultry the following procedure is recommended: Two wooden boxes should be used, one considerably larger than the other, and each having two or more holes in the sides large enough to admit rats. The poisoned bait should be placed in the bottom and near the middle of the smaller box, and the larger box should then be inverted over the other. Rats thus have free access to the bait, but fowls are excluded.

The cheapest and most effective poison is barium carbonate. This may be made into a dough with four parts of meal or flour to one part of barium carbonate. A good plan is to spread the barium carbonate upon fish, on toasted bread (moistened), or upon ordinary bread and butter.

Strychnin is effective and may be used by inserting the dry crystals in a piece of meat, cheese, or sausage, which is placed in the runways.

Arsenic is popular; the powdered white arsenic (arsenious acid) may be used as described for strychnin or barium; or a stiff dough may be made by mixing twelve parts by weight of corn meal and one part of arsenic with white of egg. An old English formula is one pound of oatmeal, one pound of brown sugar, and a spoonful of arsenic.

Phosphorus is an effective and attractive bait. The yellow phosphorus in the proportion of one to four per cent. may be mixed with glucose or other suitable material. Kitano<sup>86</sup> soaks the phosphorus into bread, which is cut into pieces containing 0.025 gm. of phosphorus per piece. The use of phosphorus is very dangerous on account of fire. Rats poisoned with phosphorus may die on the premises and decompose, contrary to the statements sometimes made in the advertisements.

The following formula is recommended as a poisonous bait for rats, mice, squirrels, etc.:

Strychnin .....	1 oz.
Cyanid of potassium.....	2 oz.
Eggs .....	1 doz.
Honey .....	1 pint
Wheat or barley.....	30 lbs.

Stir eggs well, then mix in honey and again stir. Then put in dry powdered strychnin and cyanid and stir until well mixed. Put wheat in large box or can and pour in the mixture of poison and stir until it is well distributed over the wheat. Stir two or three times during

<sup>86</sup> *Am. Jour. Trop. Dis.*, III, 12, June, 1916, p. 635.

twenty-four hours, then spread out and dry. Before putting it out for squirrels add oil of rhodium, 1 dram.

Poisons and traps reduce the number of rats but do not eliminate them. Poisons and traps find their greatest usefulness in ridding large rat-proof structures of contained rats. Starving rats by keeping food from them is one of the best methods of suppression.

**Domestic Animals.**—A well-trained dog may be relied upon to keep the farm premises reasonably free of rats. Small Irish, Scotch, and fox terriers make the best ratters; the ordinary cur and the larger breeds of dogs seldom develop the necessary qualities for ratters.

However valuable cats may be as mousers, few of them care to catch rats. The ordinary house cat is too well fed and too lazy to undertake the capture of an animal as formidable as the brown rat. Koch has advised the breeding and distribution of cats capable and willing to attack rats.

**Shooting.**—Many rats may be shot as they come out to forage about sundown. This method is particularly effective in a large building which is suddenly overrun with the rodents. The shooting of a number of them upon two or three successive nights discourages the remainder, who leave for some other happier hunting ground.

**Fumigation.**—Rats may be killed with certainty in any inclosed structure by the use of sulphur dioxid, carbon bisulphid, hydrocyanic acid gas, or carbon monoxid. The methods of evolving these substances are described in Section XII. Hydrocyanic acid gas or sulphur dioxid are particularly useful to destroy rats on board ships, in cellars, stables, sewers, and places where they abound. Enormous numbers of rats are frequently killed when ships are fumigated with sulphur dioxid. I have seen buckets full thrown overboard from comparatively small vessels. Hobdy counted 310 on a lumber-carrying schooner of only 260 tons burden. The S.S. *Minnehaha*, a vessel only nine months in commission, fumigated in London in May, 1901, yielded a bag of 1,700 rats. See pages 513 to 518.

**Carbon Monoxid.**—Carbon monoxid is an exceedingly poisonous gas. From the fact that it has no odor, it is even more hazardous in practice than hydrocyanic acid. Carbon monoxid is fatal to all forms of mammalian life, but has no germicidal properties whatever. It has been used in Hamburg<sup>87</sup> and other ports for the destruction of rats on ships.

Carbon monoxid is a colorless, odorless gas, lighter than air. It forms a stable compound with the hemoglobin of the blood—carbon monoxid-hemoglobin. For the toxic action of this gas and its other properties see page 941. The particular advantages of carbon monoxid for the destruction of rats on board ship are that it may be generated

<sup>87</sup> Nocht and Giemsa: *Arbeiten a. d. kaiserlichen Gesundheitsamte*, Bd. 20, Erstes Heft, 1904, p. 91.

cheaply, is quickly effective, and does no injury to cargo or vessel. The disadvantages are that it is poisonous and inflammable. The addition of a little sulphur dioxide to the gas makes its presence known and tends to prevent accidents. After exposure the hold must be thoroughly ventilated, and it is customary to lower a mouse in a cage for 10 minutes to be sure that it is safe for a man to enter. Divers' helmets should also be kept in readiness so that the hold may be entered in case of need.

A gas generator has been made by Pintsch which furnishes a mixture consisting of CO, 5 per cent., CO<sub>2</sub>, 18 per cent., N, 77 per cent. These gases are generated by the incomplete combustion of coke. The mixture of gases is pumped into the hold of the vessel or other compartments where it is desired. The hold should be kept tightly closed from 7 to 8 hours. Funnel gases are also serviceable.

**The Bacterial Rat Viruses.**—Rats are notoriously resistant to bacterial infection.<sup>88</sup> Even plague usually fails markedly to diminish their prevalence. An epizootic of bacterial nature, therefore, cannot be classed with the natural enemies of the rat. We are not surprised, then, to learn that the bacterial rat viruses have signally failed to accomplish their mission.

These bacterial viruses belong to the colon-typhoid group of organisms. They are either identical with or closely related to the original bacillus of mouse typhoid (*B. typhi murium*) discovered by Loeffler, or the paratyphoid bacillus, type B, or the *Bacillus enteritidis* of Gaertner, which have been associated with gastro-intestinal disorders.

The claim that these rat viruses are harmless to man needs revision, in view of the instances of sickness and death reported by various observers. The pathogenicity for man depends upon the virulence of the culture, the amount ingested, the nature of the medium in which it grows, and many other factors.

Danysz virus (*B. typhi murium*) is pathogenic for rats under laboratory conditions, but has feeble powers of propagating itself from rat to rat. It rapidly loses its virulence, especially when exposed to light and air. The result depends largely upon the amount ingested. The other viruses have proved even less satisfactory.

Under natural conditions these rat viruses may be likened to a chemical poison, with the great disadvantage that they rapidly lose their virulence and are comparatively expensive. They also have the further disadvantage that chemical poisons do not possess of rendering animals immune by the ingestion of amounts that are insufficient to kill or by the ingestion of cultures that have lost their virulence.

## SQUIRRELS AND PLAGUE

**Squirrels.**—In August, 1903, a blacksmith died of plague probably contracted from a squirrel in Contra Costa County, California. In 1904 Currie demonstrated the susceptibility of the ground squirrel to bubonic plague. In 1908 McCoy and Wherry discovered natural plague in ground squirrels. It was then learned that thousands of squirrels had died of some disease during 1904, 1905, and 1906. This epizootic was doubtless plague. It is now realized that plague has become endemic in California, in the squirrel. It is also believed that the disease has been kept alive in the endemic foci of Tibet in another rodent, the marmot (*Arctomys bobac*). The eradication of plague must, therefore, consider these and perhaps other susceptible wild animals.

California is overrun with three species of ground squirrels. The commonest is the *Citellus beecheyi*. They live in colonies in burrows or warrens. The booby owl is a frequent companion occupying the same burrow, and they probably spread the infection by carrying fleas. Squirrels become infected through fleas from each other and from rats. The squirrel flea (*Ceratophyllus acutus*) attacks man just as the rat flea does. The infection may also be conveyed to man through squirrel bites, as in the case of the child in Los Angeles studied by Stimson. Squirrels make good food for man, but since the danger has been realized the shooting or trapping of them for food purposes is now forbidden in California.

An outbreak of pneumonic plague in Oakland, California, during August and September, 1919, started with a man who went squirrel hunting in Berkeley Hills on August 11th and 13th, and took ill August 15th. The outbreak involved 14 cases, 13 of whom died.<sup>89</sup>

Plague in the squirrel may be recognized<sup>90</sup> by the gross anatomical lesions in the lymphatic glands, the liver, and lungs. The pneumonic form of the disease is common in the squirrel. Many cases are subacute or chronic. Smear preparations from squirrels dead of plague are frequently negative for plague-like bacilli. The diagnosis may, therefore, be made more surely by animal experimentation. Subcutaneous inoculation is surer than the cutaneous method, as the latter often fails on account of the comparatively few plague bacilli present in squirrel lesions.

Squirrels may be destroyed by various means. One of the most successful is to saturate cotton waste the size of an orange with carbon bisulphid and place it in the warren; then close the opening with wet

<sup>89</sup> Kellogg, W. H., An Epidemic of Pneumonic Plague. *Am. Jour. Pub. Health*, July, 1920, Vol. X, No. 7, p. 599.

<sup>90</sup> McCoy: *Jour. of Infect. Dis.*, Nov. 26, 1909, Vol. V, No. 5.

clay. Officers of the Public Health Service working in California have devised an apparatus for vaporizing carbon bisulphid and pumping the gas into the burrows. This method is reported to be much more successful than any other that has been employed. Poisoned bait, such as strychnin, phosphorus, or cyanid of potassium, is effective. Traps are not very successful, as the squirrel is wary. Natural enemies, such as the coyote, wolf, badger, skunk, mountain lion, the cobra snake, and red-tailed hawk should be encouraged.<sup>91</sup>

## THE PLAGUE

(*Peste*)

Plague is an infection primarily of rats and other rodents, secondarily of men; caused by *Bacillus pestis*. In addition to this specific definition the term plague still has a generic meaning. There is much confusion in the literature, because formerly all serious epidemics were called plague and we still speak of them as plagues.

The Philistines made offerings of golden images of the mice that marred the land to stay a pestilence II Samuel. The plague of Athens and the pestilence in the reign of Marcus Aurelius, according to Payne, may not have been this disease. Epidemics of varying severity occurred in Europe for over 1,100 years—from the sixth century in the days of Justinian to the middle of the seventeenth century. The most devastating was the "Black Death" of the fourteenth century which overran Europe and destroyed one-fourth of the population. The disease gradually subsided and disappeared from Europe and became endemic in a few remote parts of the world (page 350). We thought it had passed away, when suddenly, in 1894, it reappeared at Hongkong and from there again spread over the world. This recrudescence of a disease thought to be extinct is one of the most striking facts in epidemiology.

The recent pandemic is the most widespread of all, having been carried to the four quarters of the globe by trade and travel. It is quite as virulent as the Black Death of the fourteenth century; thus, from the autumn of 1896 when plague first gained a footing at Bombay, to the end of 1917, about 10 millions of people are reported to have died of the disease in India:—In 1904, there were 1,143,993 deaths from plague; in 1905, 1,069,140; in 1907, 1,315,892; in 1908, 156,480; in 1909, 178,808; in 1914, 296,623; in 1915, 438,866; in 1916, 276,195;

<sup>91</sup> In this chapter material has been freely drawn from "The Rat and Its Relation to the Public Health," Public Health and Marine Hospital Service, 1910, particularly articles by Lantz, McCoy, Brinckerhoff, Banks, Stiles, Rucker, Creel, Holdy, Kerr, and Rosenau. This book may be obtained by addressing the Surgeon-General or the Superintendent of Public Documents, Washington, D. C.

in 1917, 537,404. The Manchurian outbreak in the winter of 1910-11 was the pneumonic type of the disease; it was virulent and extensive, and claimed over 45,000 persons in a few months.

In 1664-65, the Black Death in London carried off 70,000 of a population then numbering 500,000. A graphic description is given by Defoe in "A Journal of the Plague Year." Numerous references to the disease will be found in Pepys' Diary. Benvenuto Cellini describes his own case in his autobiography. The disease profoundly affected the economic, social and political history of Europe. Plague started in Stratford-on-Avon in July, 1564, when Shakespeare was a baby three months old. From July to December of that year, 237 deaths are recorded in the parish register of the little vicarage of Avon. The infection swept away entire families. Fortunately, not a Shakespeare is on the list. How much has mankind lost throughout the world's long history by the untimely death of genius on account of preventable infections!

There are now four endemic foci in the United States—one on the Pacific coast and three in the Gulf states. The number of cases in the United States and their occurrence is shown in the table on the following page.<sup>92</sup>

In considering the prevention of plague it is necessary to recognize that the different types of the disease are spread in different ways. At least three clinical types are now recognized: (1) bubonic, (2) pneumonic, and (3) septicemic.<sup>93</sup> In the bubonic and septicemic types of the disease the plague bacillus is locked up in the glands, blood, and other tissues and organs of the body, and is not eliminated in the usual excretions. These forms of the disease are therefore, not "contagious," but are spread mainly through the agency of the flea. On the other hand, in the pneumonic type of the disease plague bacilli are contained in enormous numbers in the sputum. The disease is transmitted directly by close association with a patient having plague pneumonia. The pneumonic type of the disease usually follows when the infection is taken into the system through the respiratory channel; on the other hand, it may result from infection through a flea bite.

Bubonic plague is an insect-borne disease and has an entirely different epidemiology from pneumonic plague, which is a contact infection.

Pneumonic plague may assume epidemic proportions, especially in the cold weather and under circumstances where people come in close association. This was the case in the Manchurian epidemic of 1910-1911 which occurred during the winter and was one of the most virulent

<sup>92</sup> From data collected by Dr. G. W. McCoy.

<sup>93</sup> Occasionally other varieties occur in which the chief manifestations are in the skin and subcutaneous tissues, or in the intestines, causing diarrhea. In the latter case the infection is excreted in the feces.

## PLAGUE—HUMAN CASES IN THE UNITED STATES

\* This includes 17 cases of squirrel origin.

epidemics of modern times, the mortality being over 90 per cent. Epidemics of pneumonic plague are restricted to northern climates, as northern Asia and the northern higher regions of India. A limited outbreak was reported in 1919 from California, which started from an infected squirrel.

Teague and Barber<sup>94</sup> explain the rapid spread of pneumonic plague in Manchuria and the failure of this type of the disease to spread in India upon the assumption that in the warm temperatures of India the droplets quickly dry and the plague bacilli soon die, whereas in Manchuria the temperature and humidity do not favor evaporation and hence the droplets of sputum persist longer in the cold atmosphere and the plague bacilli remain alive longer.

The *Bacillus pestis* (Yersin, 1894) has more than fulfilled Koch's laws. Several accidents in which pure cultures have been inoculated into man, producing all the symptoms and lesions of the disease, have added to the proof that this organism is the cause of plague (Vienna, 1898, Ann Arbor, 1902, and also in laboratories in Russia, Berlin, and Japan). The plague bacillus is comparatively easy to isolate and grows readily on artificial culture media, and has characteristics that readily distinguish it from all other species. It is a short rod with rounded ends, with a tendency to bi-polar staining, not motile, decolorized by Gram's method, and grows well at room temperature though less luxuriantly than at 37° C.

Recognition of the plague bacillus rests upon the following characteristics: (1) Curious involution forms upon salt agar within 24 hours; (2) stalactite growth in liquid media; (3) characteristic lesions produced by experimental plague in guinea-pigs, rabbits, rats, etc. Kolle's method consists in rubbing the material containing the plague bacillus upon a shaved area of the skin of a guinea-pig. The plague bacilli penetrate the skin, leaving other organisms behind. The skin of the guinea-pig thus acts as a differential filter. (4) The final test of the identity of the plague bacillus is the fact that its pathogenicity may be neutralized by the use of antiplague serum.

The *Bacillus pestis* does not live a saprophytic existence in nature. It is readily killed by drying, sunlight, heat, and the usual germicides. The organism does not live long in the soil or upon the floors of houses, as was once commonly supposed. There is, therefore, comparatively little danger from these sources.

**Immunity.**—One attack of plague usually protects for life. Occasionally second attacks are noted in the same person. In such cases the second attack is usually mild. This is an old observation and led

<sup>94</sup>Teague, O.: "A Further Note on the Influence of Atmospheric Temperature on the Spread of Pneumonic Plague," *Philippine Jour. Sc., B., Tropical Med.*, 1913, VIII, 241.

to the employment of persons with a plague history or a plague scar in hospitals and laboratories.

Artificial immunity of either an active or passive nature may be acquired by various procedures. The passive immunity produced by the injection of antiplague serum lasts only about three to four weeks. The active immunity produced by vaccination of cultures may be depended upon for about six months.

*Haffkine's prophylactic* consists of a killed culture of the plague bacillus, which is injected subcutaneously. Haffkine used a bouillon culture, six weeks old, grown at 25-30° C. and killed at 65° C., for one hour. One-half of one per cent. of phenol is then added. From 2 to 3.5 c. c. (this was later increased to 20 c. c.) of this vaccine are injected subcutaneously. Ten days later a second injection of a still larger amount is given.

In twelve districts in India 224,228 persons were inoculated with Haffkine's prophylactic. Of these 3,399 took the disease. Of 639,600 not inoculated in the same districts 49,430 were attacked. C. J. Martin concludes that the chances of subsequent infection are reduced four-fifths, and the chances of recovery are 2.5 times as great as in the cases of the non-vaccinated.

The German Plague Commission prepared their prophylactic vaccine from a fresh virulent agar culture, suspending the bacilli in salt solution or bouillon. The organisms are killed at 65° C. for one to two hours, and 0.5 per cent. phenol added. The amount injected represents one agar culture.

Lustig and Galeoti extract the immunizing substance from the bacterial cell (endotoxin) with weak potassium hydroxid. This nucleoprotein is collected and dried, and thus permits of exact dosage. The amount injected is two to three milligrams of the dry extract dissolved in water.

Terni and Bandi recommend the peritoneal exudate of plague-infected guinea-pigs, sterilized fractionally at 50° C., and the addition of 0.5 per cent. of phenol, 0.25 per cent. sodium carbonate, and 0.75 per cent. sodium chlorid.

Shiga prefers a combined active and passive immunity produced with killed cultures and antipest serum, because this mixed immunizing process has the advantage of producing milder reactions.

Kolle and also Strong started out from the principle that a much higher degree of immunity is produced by living microorganisms than dead ones, and recommended the use of live attenuated cultures. Strong has a strain, an entire agar culture of which may be injected into man without harm. In Manila 42 persons were given a preventive inoculation with this culture.

The reactions which follow vaccination with a plague culture,

whether alive or dead, are sometimes marked. The symptoms consist of a rise in temperature to 39° C., malaise, depression, and headache, and swelling and pain at the site of the inoculation. The symptoms usually pass away in 24 to 48 hours.

The production of an active acquired immunity has a distinct practical usefulness in the prevention of the disease, although it cannot take the place of rat and flea eradication. It has been used on a large scale by Haffkine in India, and to a lesser extent by others in many parts of the world during the recent plague pandemic. Those who get plague after Haffkinization usually have a mild form of the disease, which, in the experience in India, rarely results in death. It is of first importance in protecting small communities, on shipboard, in camps and barracks, at quarantine stations, in plague laboratories, among rat brigades, as well as for physicians, nurses, and others who are exposed.

McCoy and Chapin<sup>95</sup> state that there is no evidence indicating that vaccination for plague has ever controlled an outbreak. A community should not be allowed to delude itself into the belief that plague may be controlled in this manner.

*Yersin's serum* is obtained from a horse that has received repeated injections of plague cultures; at first killed plague cultures, afterward living bacilli, are used. At most this antitoxic serum is weak; it has feeble and transient protective properties, and slight if any curative power. Very large quantities must be administered early in the disease to obtain any effect at all.

**Endemic Foci.**—There are four historic endemic foci in which plague has slumbered for ages. One is on the eastern slope of the Himalayas, in the province of Yünnan. The great epidemic in Hongkong in 1894 came from this center. A second endemic focus near, and perhaps connected with the first is on the western slope of the Himalayas. From here the infection was carried to Bombay in 1896, where it still prevails. A third plague focus exists from about the center of Arabia to near Mesopotamia. From here the infection was dragged to Samarkand, the Black Sea, and Persia. The fourth endemic area was discovered by Koch in 1898 in the interior of Africa, near the source of the White Nile in Uganda. We must now add to this a fifth endemic focus, for plague has obtained a foothold in California in the ground squirrels, which will take years of well-directed energy to control. The disease also has gained a foothold in the Gulf States—Louisiana, Texas and Florida; and is endemic in many parts of India, Africa, South America and Asia.

**Management of a Plague Epidemic.**—The handling of a plague epidemic is conducted along two definite lines of activity. One is to find and care for the human cases, the other consists in a warfare against

<sup>95</sup> *U. S. Public Health Rpts.*, Vol. XXXV, No. 28, July 9, 1920, p. 1647.

rats. The organization and general management of a plague campaign do not differ radically from similar work in other epidemics (see page 495). Cases of the disease must be sought for and early diagnosis confirmed; all deaths from no matter what cause must be investigated, and the body examined by an expert before burial is permitted. A bacteriological laboratory is a *sine qua non*. Cases of the disease should be isolated and the usual disinfection of excreta and surroundings exercised. Particular care must be taken that the isolation wards are vermin-free. The place from which the case is removed should be given a preliminary disinfection with sulphur dioxid or other substance that may be depended upon to kill rats and fleas, and a search made in the neighborhood for secondary cases both in man and rodents.

The campaign against the rat is expensive and difficult, but must be vigorously prosecuted to insure success. The rat warfare may be briefly summarized as a simultaneous attack upon the habitation and food supply of the rat; the destruction of rat burrows and nesting places; the separation of the rat from his food supply by concreting and screening such places as stables, warehouses, markets, restaurants, etc.; the prevention of the entry of the rat into human habitations by the use of concrete, wire netting, or other barriers; and the use of poisons, traps, etc. For further consideration concerning rats and their eradication see page 338. All the rats that are caught in traps or found dead are brought to the bacteriological laboratory, where they are examined and careful records kept concerning the species, the location, the place where the rat was caught, the character of the infection, etc. As it is a hopeless task to exterminate rats from a large city, Heiser has proposed a practical plan which proved effective in Manila. A list of the places in which the plague-infected rats were found was made. Each was regarded as a center of infection. Radiating lines, usually five in number, were prolonged from this center, evenly placed like the spokes of a wheel. Rats were caught along these lines and examined. Plague rats were seldom found more than a few blocks away. The furthestmost points at which the infected rats were found were then connected with a line, as is roughly shown in the diagram, Figs. 44 and 45. The place inclosed by the dotted line was regarded as a section of infection. The entire rat-catching force was then concentrated along the border of the infected section, that is, along the dotted line. They then commenced to move toward the center, catching the rats as they closed in. Behind them ratproofing was carried out. One section after another was treated in this way, until they had all been wiped out. Once weekly thereafter rats were caught in the previously infected sections and at other places, especially those which had been infected in years gone by. Since the above system was adopted plague has disappeared in the city of Manila, and at a cost of only a small

fraction of that of a general rat extermination campaign. A campaign along these same general lines has also been successful in New Orleans.

**Quarantine.**—Plague infection is frequently carried overseas in vessels. When this happens it is more apt to be due to the disease in the rat than man. Maritime quarantine, therefore, finds its greatest justification in keeping out plague. To be successful, measures must be directed almost entirely against the rat. Rats may be kept down on board a vessel by the frequent use of sulphur dioxid. All vessels

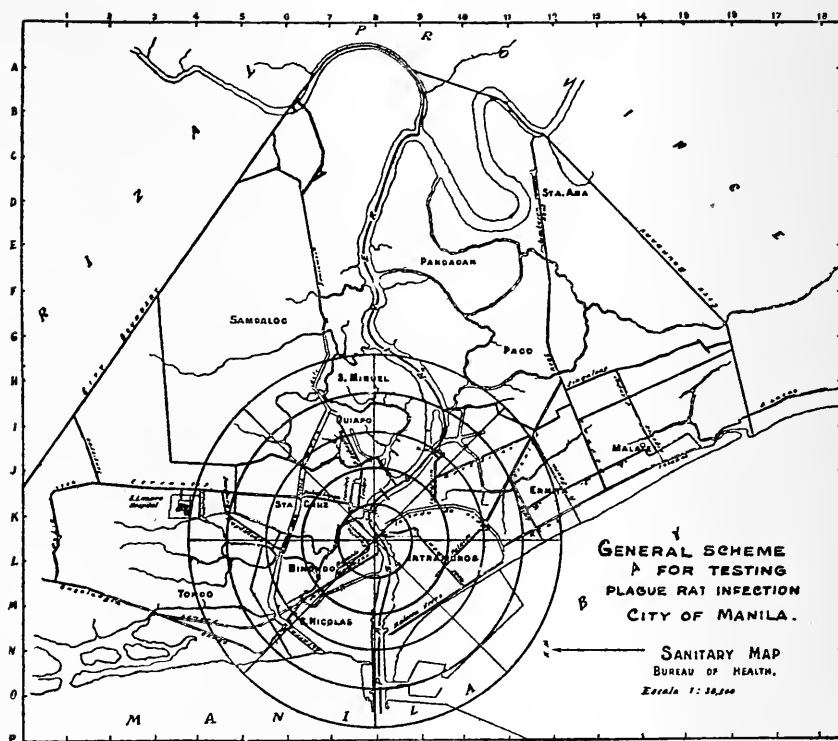

FIG. 44.

trading with a plague-infected port should have each cargo compartment fumigated with this gas, or better, hydrocyanic acid, at least when it is empty, at the port of departure. The vessel must be again fumigated on arrival. Both at the infected port and at the port of arrival, care must be taken to prevent the ingress and egress of rats. The period of detention of the personnel for a plague ship is seven days. For further details concerning quarantine see page 498.

**Prevention—Summary.**—The principles and many of the details for the prevention of plague have been stated in the foregoing pages, and need not be repeated.

Personal prophylaxis consists in avoiding the infected regions and guarding against flea bites. Physicians and nurses should remember that the pneumonic form of the disease is highly "contagious" in the ordinary sense of the term. Attendants and persons who come in contact with such cases may protect themselves with Haffkine's prophylactic. Individual measures to guard against droplet infection, such as the wearing of masks or veils of cheesecloth, may be resorted to. The bubonic and septicemic forms of the disease are not, as a rule, directly

FIG. 45.—ISOLATED PLAGUE-INFESTED CENTER, MANILA, P. I.

communicable, and, therefore, the preventive measures recommended for typhoid fever are effective.

The ordinary germicidal solutions, such as bichlorid of mercury, 1-1,000, carbolic acid, 2½ per cent., formalin, 10 per cent., are effective against the *Bacillus pestis*. Of the gaseous disinfectants, sulphur dioxide is preferred, because it not only kills the frail plague bacillus, but also destroys rats, fleas, etc.

Cases of plague should be isolated in a well-screened room otherwise free of insects. Fabrics and other objects which become contaminated with the discharges should be thoroughly disinfected by proper methods.

It is important to have prompt reports of all cases of suspected

plague, and the diagnosis must be confirmed by bacteriological methods. In all plague centers there should be a special hospital and also a laboratory where diagnostic work may be carried on; this is an essential part of the equipment for a successful campaign. A traveling laboratory organized like a flying squadron for quick service should be provided to furnish this service wherever it may be demanded.

The prevention of plague, after all, is reduced to warfare against rats and fleas. This has been fully discussed. All seaport towns having communication with plague countries should examine rats caught about the wharves and other places for plague. This, in fact, should be one of the routine duties of the port sanitary authorities. Plague may slumber in the rats for years before human cases occur. Other preventive measures are obvious from the nature of the infection and its mode of transmission, or have already been stated in the preceding pages.

Plague quarantine, see page 505.

## TICKS

Ticks belong to the family Ixodidae; quite a number of different species are known to attack man.

Ticks, or wood lice, are not true Insecta, but belong to the acarines which include the mites, and are closely allied to spiders and itchmites (scabies). Ticks have an unsegmented body with eight legs in the adult stage and six legs in the larval stage. In some of their habits they resemble bedbugs. So far as is known, they take no vegetable food, but live on blood. Ticks are ectoparasites of man and many animals. They frequently hang tenaciously to the skin, in which they partly bury themselves. If covered with oil or vaselin, thus closing their breathing pores situated behind the fourth pair of legs, they may be induced to release their hold. If pulled off roughly the head (capitulum) is likely to break off and remain in the skin. Sulphur in some form is useful to destroy ticks in the adult stage. Sulphur ointment is particularly obnoxious to this group of parasites. Arsenic and crude oil also act as poisons to the tick, and may be used by local application. McCormack states that tick bites cause paralysis.

The life cycle of the tick consists of four distinct stages, viz., egg (embryo), larva, nymph, and adult. The eggs are invariably deposited on the ground in large masses. The larvae which emerge from the eggs are minute six-legged creatures. The larvae attach themselves to a suitable host, upon which they feed, then usually drop to the ground and molt, becoming nymphs. The nymphs have eight legs. The nymph waits until it can attach itself to a host, engorges blood, usually drops,

molts its skin, and becomes adult. Ticks take at least two, and sometimes four or five, years to mature. They hibernate during the winter. They prefer shady places, and are destroyed by sunshine; hence, clearing the land and cultivation are good measures of eradication. The life history of the tick differs from the mosquito in that the larval and pupal stages are not aquatic.

It was first shown by Smith and Kilborne that in the case of Texas fever the microörganism within the adult tick passes into the egg and is, therefore, transmitted "hereditarily" to the next generation. The infection of Rocky Mountain spotted fever, of canine piroplasmosis, and probably also that of African tick fever, is also transmitted by the female to the next generation. Tick-borne diseases are not always transmitted in nature in this way. The virus may be transferred directly by the larva, the nymph, or the adult. Thus, some ticks leave their host repeatedly, and the parasites they draw from one animal may be injected into another animal either during the same or at a subsequent stage in the development of the tick.

Ticks upon domestic stock may be controlled by dipping, spraying, or by hand methods. The arsenical dip has practically displaced all others for the destruction of ticks in the various parts of the world. Arsenical solutions containing sodium arsenite in amounts equivalent to about 0.2 per cent. arsenious oxid ( $\text{As}_2\text{O}_3$ ), or less according to the frequency of dipping and other conditions, give the best results in killing ticks without injury to the stock. This strength of arsenic, however, will not kill or prevent egg-laying by all the engorged females. Crude petroleum oils have been used to a considerable extent. They are more expensive than the arsenical dip, and dangerous to cattle under some conditions. Serious losses have followed the use of heavy oils in dry regions, or where it has been necessary to drive the cattle any considerable distance after dipping.

A commonly used formula for arsenical dip is as follows:

Sodium carbonate (sal soda).....	24 lbs.
Arsenic trioxid (white arsenic).....	8 lbs.
Pine tar .....	1 to 2 gals.
Water .....	sufficient to make 500 gals.

The above formula may be used when treatments are given not oftener than every two weeks, but in some tick-borne diseases more frequent dippings are necessary owing to peculiarities in the life histories of the various species of ticks, and weaker solutions, although less effective in destroying ticks, must be used to avoid injury to the cattle.

Sometimes dipping is not practical. Instead of driving cattle considerable distances to dipping vats it will be found sufficient to treat

them thoroughly by hand methods. The procedure consists simply in applying the arsenical mixture liberally by means of rags, mops, or brushes, or by means of spray pumps. Crude oil may be used by hand instead of the arsenical solution.

The following diseases transmitted by ticks will be given brief consideration: Texas fever (*Margaropus annulatus*), South African tick fever (*Ornithodoros savignyi*), Rocky Mountain spotted fever (*Derma-centor venustus*), and relapsing fever (*Ornithodoros moubata*); although it is probable that the latter disease is also transmitted by the *Argas persicus* and perhaps other biting insects.

### TEXAS FEVER

Texas fever or splenetic fever is also known as bovine malaria, tick fever, and hemoglobinuria. The disease does not affect man. It is confined to cattle, and is of very great economic importance. Texas fever is an infection which should be understood by all sanitarians, on account of its scientific and historic importance. The cause of this infection and its mode of transmission were ascertained in 1893 by Smith and Kilborne. The discovery that the tick is the intermediate host of Texas fever opened an entirely new principle in the sanitary sciences.

Texas fever is caused by a protozoön parasite. This parasite was first named *Pyrosoma bigeminum* on account of the twin-like, pear-shaped forms commonly seen in the red corpuscles. This genus was changed by Patton in 1895 to *Piroplasma*. These terms having been preoccupied, the present name of the parasite is *Babesia bigemina*.<sup>96</sup>

The contagium is carried by the cattle tick, *Boöphilus bovis*, now *Margaropus annulatus*. This tick lives upon the skin and feeds upon the infected blood, becomes sexually mature at the last molt; the female drops to the ground and lays about 2,000 eggs; the newly hatched larvae attach themselves to the skin of a fresh host, which they infect. This explains the long extrinsic period of incubation in this disease, 40-60 days, 30 days of which are required for the development of the larvae and the remainder for the development of the parasite within the host.

### ROCKY MOUNTAIN SPOTTED FEVER

Rocky mountain spotted fever is an interesting infection, with a very limited geographic distribution. The symptoms closely resemble those of typhus fever, including an eruption, first macular then petechial. This may go on to gangrene of the skin, due to thrombi of the peripheral vessels. Irritability and hyperesthesia of the skin are common symptoms

<sup>96</sup> These various names are given for the reason that they are all found in the literature.

and are due to infiltration of the peripheral nerves. There is no leukocytosis, but an increased number of mononuclear cells.

The disease is very mild in Idaho and very virulent in Montana, which has a case fatality as high as 90 per cent. About 500 cases occur in the United States a year. The disease prevails especially in the spring.

Rocky Mountain spotted fever may be distinguished from typhus fever in the guinea-pig:—After intraperitoneal injection of infected blood, the period of incubation in Rocky Mountain spotted fever is 3 days, while in typhus it is 9 to 11 days; typhus does not show the scrotal and foot lesions of Rocky Mountain spotted fever; the virus of typhus is much less virulent for guinea-pigs; there is no cross immunity:—the two diseases are therefore distinct.

FIG. 46.—THE TEXAS FEVER TICK (*Margaropus annulatus*).

Rocky Mountain spotted fever is widely spread over seven states in the Rocky Mountain region; namely, Colorado, Idaho, Montana, Nevada, Utah, Oregon, and Wyoming, and is also found in California, South Dakota, Washington and British Columbia. The disease has been studied especially in the Bitter Root Valley of Montana, where it is limited to the western slope.

Wilson and Chowning first suggested that the tick acts as the carrier of Rocky Mountain spotted fever. This was proved by Ricketts in 1906, who showed that the particular tick is *Dermacentor andersoni*,<sup>97</sup> *Dermacentor modestus* and *Dermacentor marginatus* also transmit the infection. The infection may be transmitted by the larva, the nymph, and both the adult male and female ticks. The disease is transmitted to susceptible small animals by the larvae and nymphs; but the mouth parts of these immature forms are probably not strong enough to feed on man and other large animals, which are infected by the adult ticks. The infection is also transmitted "hereditarily" through the ticks to their larvae. The disease has been transmitted from man to monkey

<sup>97</sup> Also called *D. occidentalis* and *D. venustus*.

and the guinea-pig, and also from monkey to monkey and from guinea-pig to guinea-pig. Rabbits, ground squirrels, woodchucks, and other animals are susceptible.

FIG. 47.—ROCKY MOUNTAIN SPOTTED FEVER TICK. (*Dermacentor venustus*).

1, Adult female, unengorged, dorsal view; 2, Adult male, dorsal view; 3, Adult female, unengorged, ventral view; 4, Adult male, ventral view; 5, Adult female in act of depositing eggs.

Infected ticks have actually been found in nature. Ricketts found one out of 296; Maver, 2 out of 402; and McClintic, 6 out of 1,037. The ticks were collected from known infected districts and fed on

guinea-pigs in groups. McClinton died of Rocky Mountain spotted fever while studying the disease.

Mayer<sup>98</sup> has proved by experiment that different species of ticks collected from various regions [*Dermacentor marginatus* (Utah), *Amblyomma americanus* Linnaeus (Missouri), and *Dermacentor variabilis* (Mass.)] are able to transmit the virus of Rocky Mountain spotted fever. The inference is that the disease may find favorable conditions for its existence in localities other than those to which it is now limited.

One attack of the disease establishes a very high degree of immunity. No authentic case of a subsequent attack in man is known, and laboratory animals have always been found completely immune after a primary infection. The blood serum of recovered cases contains protective properties of a rather high degree for guinea-pigs (King). The virus is not filterable through a Berkefeld filter.

Ricketts found "bodies" in the blood of human and experimental cases and also in the tissues and eggs of infected ticks. These observations have been confirmed by Wolbach,<sup>99</sup> who finds bacillus-like bodies in the lesions of Rocky Mountain spotted fever. The characteristic form is a short rod, in pairs and clusters, growing in great numbers in the lesions of the blood vessels, testicle, skin, and subcutaneous tissues. Wolbach later identified these bodies as *Rickettsia*, which are described on page 372.

This organism has not been grown in artificial culture media. It invades all the tissues of the tick, even the ova and the spermatozoa, which accounts for "hereditary" transmission of the infection. In man these Rickettsia bodies are mainly localized in the smaller peripheral blood vessels, causing proliferating endarteritis.

The prevention of Rocky Mountain spotted fever is directed entirely against the tick. Ticks are to be avoided in the infected region. If it is necessary to work in the fields and woods and about animals where these ticks abound, the bites should at once be cauterized with strong carbolic acid. In endemic regions the entire body and clothing should be examined twice daily for ticks.

The ultimate control of Rocky Mountain spotted fever depends upon the suppression of the *Dermacentor andersoni* and related ticks in infected areas. This, perhaps, is not so hopeless a task as may at first seem likely.<sup>100</sup> Henshaw and Birdseye<sup>101</sup> found ticks either in the immature or adult stage upon twenty species of five hundred mammals

<sup>98</sup> *Jour. Infect. Dis.*, April 12, 1911.

<sup>99</sup> *Journal of Medical Research*, March, 1916, Vol. XXXIV, 1, pp. 121-126, and XLI, 1, Nov., 1919.

<sup>100</sup> Fortunately the *Dermacentor andersoni* is the only tick in the endemic region which attacks man.

<sup>101</sup> U. S. Dept. of Agr., Bureau of Biol. Survey, *Cir.* 82.

examined in and around Bitter Root Valley. The mammalian hosts of fever ticks fall naturally into two groups: those that harbor chiefly adult ticks and those that harbor the younger stages. In the former class belong mountain goats, bears, coyotes, badgers, woodchucks, and possibly elk, deer, mountain sheep, rabbits, and domestic stock, such as horses, cattle, and sheep. Those of the second class harboring the nymphs and larvae are mainly rodents and comprise ground squirrels, woodchucks, chipmunks, pine squirrels, mice, and wood rats. These smaller animals are too agile to permit the adult ticks to remain upon them.

Unquestionably the great bulk of fever ticks (*Dermacentor andersoni*) which become engorged in the Bitter Root Valley do so on domestic stock—horses, cattle, sheep, and sometimes dogs. They obtain the ticks from the pastures and other uncultivated land infested by wild animals. It is obvious, therefore, that, if the domestic animals in the valley are rendered tick-free by dipping, spraying, or by some other equally effective method, the chances of the infection of human beings will be vastly lessened.

The measures proposed for the eradication of the tick are as follows: Clearing and cultivation of tillable land; burning over of foothills and "slashings"; killing of small wild mammals; dipping of domestic animals in arsenical dip; spraying and removing ticks by hand from domestic animals. Each one of these measures has a rational basis in the bionomics of the tick *Dermacentor*, but although all of these methods have been attempted on the west side of the Bitter Root Valley for three years or more they have not greatly diminished the number of ticks to be found nor the number of deaths from spotted fever. The extent and inaccessibility of the infested territory, and the consequent expense have rendered the problem difficult. Fricks<sup>102</sup> recommends sheep grazing to diminish the number of ticks, for the reason that ticks die upon sheep, and many of the engorged females are not fertilized on account of the difficulty experienced by the males in propelling themselves through the thick wool in search of the females.

McClintic infected Rhesus monkeys and guinea-pigs with spotted fever and treated them with the following drugs: salvarsan, sodium cacodylate, and urotropin. The results obtained, however, do not indicate that any of these drugs possess any value whatever either as a prophylactic or in the treatment of spotted fever, but, on the contrary, their administration seems on the whole rather to intensify the severity of the disease in the animals compared with the course of the disease in the controls.<sup>103</sup>

## JAPANESE RIVER FEVER

Japanese river fever occurs along the river bottoms with a preference for sandy soil. Clinically, it resembles typhus fever. It is transmitted by a small mite (*Leptus akamushi*) which lives upon field mice. The field mouse is the reservoir of the infection. The disease also occurs in Sumatra and Formosa and probably in China. It is also known as tsutsugamushi disease.

## RELAPSING FEVERS

Relapsing fever, also called famine fever, tick fever, and seven-day fever, is found upon all the five continents of the globe. Epidemics of this disease have been reported, especially from Ireland and Russia. The infection prevails in India, where Vandyke Carter of Bombay made his classic investigations. Relapsing fever was epidemic in New York and Philadelphia in 1869. It has not reappeared in epidemic form, but cases occasionally occur in various parts of the United States. The disease has receded from civilization where sanitation is practical and hygiene is observed.

The term "relapsing fever" includes a group of tropical, febrile infections caused by different, but very closely allied, spirochetes—*spirochaudinniae*. The European relapsing fever is caused by *S. recurrentis* and transmitted by bedbugs and lice. The relapsing fevers of East and West Africa are caused by *S. duttoni* and transmitted by the tick (*Ornithodoros moubata*). The North African, or Algerian relapsing fever is caused by *S. berbera* and is transmitted by lice (*Pediculus vestimenti* and *Pediculus capitis*). The relapsing fever of Asia and India is caused by *S. carteri* and is transmitted by lice. These various spirochetes resemble each other morphologically, but show a difference in pathogenicity to laboratory animals and are further distinguished from each other by specific agglutinins.

Relapsing fever is characterized by sudden onset, intense frontal headache and pains of back and limbs. The fever continues from three to five days and falls by crisis. The temperature remains normal for about a week, when the fever repeats itself. There may be four or five such relapses, sometimes ten. The spirochetes are found in the peripheral blood only during the febrile period.

Obermeier in 1868 discovered the "spirillum" in the blood—*Spirillum*<sup>104</sup> *obermeieri*. Carter and Koch in 1878 showed that the infection may be transferred to apes by the inoculation of the blood of a patient. Münch and Moczutkowski transferred the disease by the inoculation of relapsing fever blood to healthy individuals. Koch and also Dutton and

<sup>104</sup> *Spirillum* was changed to *spirochaeta* and then to *spirochaudinni*.

Todd succeeded in demonstrating that the spirochetes of African relapsing fever multiplied in the tick (*Ornithodoros moubata*), and that the bite of this tick may convey the disease to healthy men. The spirochetes are found in the coxal glands and in the feces of the tick, which is rubbed into the wound made by the tick bite. Other insects, as bedbugs, fleas, biting flies, and lice, may convey the infection. Lice do not infect by biting, but when the insects are crushed and rubbed into a scratched surface of the skin.

Leishman<sup>105</sup> has demonstrated that the *Spirochaeta duttoni* may be transmitted "hereditarily" in the tick. He has obtained positive results in the second generation, the bites of which were infective for mice and monkeys. Attempts to carry the infection to the third generation in the tick have so far failed. Leishman considers the hereditary transmission of the infection as biological evidence that the spirochetes belong to the protozoa rather than the bacteria.

Schuberg and Manteufe<sup>106</sup> found that a temperature of 22° C. is not favorable for the spirochete in the *Ornithodoros moubata*. This was shown by experiments upon rats in which the infection through the bite of the tick disappeared more quickly at 22° C. than at higher temperatures.

One attack protects against subsequent attacks. Second attacks occur among negroes in Africa after years but are very light. The only susceptible animals are man, the apes, mice, and rats.

The prevention of relapsing fever is based upon sanitation of the environment and personal and domestic cleanliness and the avoidance of tick and other bug bites. Personal prophylaxis depends upon keeping aloof from vermin-infested places, especially where the disease prevails. Manson suggests that a mosquito net, a vermin-free bed well off the ground, and a night light are indispensable in Africa, where the nocturnal habits of the *Ornithodoros moubata* render the hours of sleep especially dangerous. This tick has habits somewhat similar to those of a bedbug, and lives in cracks of the walls and floors of the native huts. Salvarsan is a specific remedy.

## LICE

Lice are degraded, wingless insects, and are divided into two groups according to their method of feeding. The *Mallophaga* included biting lice, like the bird lice which feed on the hair and feathers of animals, but do not suck blood. As far as is known, these lice do not transmit disease. The *Anoplura*, or sucking lice, feed upon blood, and is the group concerned in the transmission of disease. Lice do not travel much,

<sup>105</sup> *Lancet*, Jan. 1, 1910, Vol. I, p. 11.

<sup>106</sup> *Zeitschr. f. Immunitätsforschung*, Orig. Bd. 4, 1910, p. 512.

and keep fairly close to one host, so they are not as dangerous as some more active parasites.

Human lice belong to three species: *Pediculus capitis*, head lice; *Pediculus vestimenti* or *corporis*, clothes or body lice; *Phthirus pubis*, pubic or crab lice. Nuttall<sup>107</sup> and Bacot<sup>108</sup> regard the head louse and clothes louse as races of the same species, and so Nuttall united them under the title *Pediculus humanus*, designating the head louse as *capitis* and the clothes louse as *corporis*.

*Pediculus corporis* is often called the "body louse" or "clothes louse," or the "grayback" of Civil War days, or "cootie" in the World War. This louse, also known as *Pediculus vestimenti*, is a parasite which depends upon human blood for sustenance and man's body and clothing for prolonged life and reproduction. The size varies with its maturity; a newly hatched louse is about the size of a pin head, while a full grown, well fed louse is about one-sixth of an inch in length. The louse has a smooth, hard, chitinous covering, which is impenetrable to most chemicals.

The body is divided into head, thorax and abdomen. At the sides of the head are two antennae, the mouth has a long sharp stylet or stabber which is used for puncturing the skin. This stylet consists of three parts which are so formed as to make a hollow tube through which the blood flows. Attached to the thorax are six legs which are joined, and at each end is a single large claw. The abdomen is divided into six or eight segments. The terminal one is indented in the female and rounded in the male. The abdomen of the female is broader than that of the male. There is some evidence that there are more females than males. Both sexes bite and convey disease.

The life histories of *Pediculus capitis*, *P. corporis*, and *Phthirus pubis* are similar, in that the insects, after emerging from the egg, undergo three molts before attaining sexual maturity.

The eggs or nits are laid on fibers of clothing or body hair. They prefer to lay eggs on rough material such as felt, wool or flannel, but will deposit eggs on silk. The eggs are ovoid, about 1/25 of an inch long, with a granulated cap or operculum; they are firmly cemented to the hair. The freshly laid egg is almost transparent, but as the embryo develops it assumes a yellowish color. The empty shell is hard and remains attached after the louse has emerged. The shell and the cement is resistant to chemicals, no solution will remove it without first destroying the hair or fiber to which it is attached. At the temperature which ordinarily exists between the skin and the clothing, the eggs hatch in from seven to ten days, but if kept in a cooler atmosphere, the incubation period is lengthened. The first molt occurs after two days; the second,

<sup>107</sup> *Parasitology*, IX, 293; X, No. 1; X, No. 4; X, 375-382; X, 383.

<sup>108</sup> *Brit. Med. Jour.*, 1, 788-9, June 3, 1916.

two days later; and the third, after three days. A complete cycle from egg to egg takes about sixteen days.

Oviposition in *Pediculus humanus* commences twenty-four to thirty-six hours after the emergence of the female from the third larval skin. The number of eggs laid depends upon the food supply and the temperature at which the female is maintained. Under optimum natural conditions, three hundred eggs represent the normal number which a female is capable of laying. Bacot<sup>109</sup> states that a female louse under ideal conditions might have four thousand offspring during her lifetime. The average life of a louse is from thirty-five to forty days, probably a little less for the males. Development of eggs is eight days at 32° C., which is the optimum temperature. This period may be lengthened or shortened by varying the temperature. Therefore, persons who remove their clothing at night will become less heavily infested than those who wear their clothing continuously. The periodic cooling of the clothing and contained lice leads to their progeny being materially reduced.

Lice feed immediately after emerging from the egg. A young louse will die within twenty-four hours if no food is obtainable, while a well fed louse can live ten days away from its host. Lice feed many times during the day. They feed most frequently at night when the host is at rest. When lice become ravenous with hunger they feed to excess and may rupture their intestinal canal. The louse depends upon the salivary secretion to dilate the capillaries so that blood flows freely. While feeding, the insect passes excreta, which contains a large proportion of undigested red blood cells.

Vermin infestation is spread either by contact with infested persons themselves, their clothing or their personal effects. One vermin-infested man may spread lice to many of his associates. The soldiers abroad believed that trenches and dugouts were "lousy" and that they obtained their infestation from them. This was not exactly true, for the infestation was obtained owing to the overcrowding in these places. Lice desert their host when the person has fever or dies.<sup>110</sup> In the first instance the excessive heat drives them off, and in the latter the lack of food supply. Lice may be dislodged by brushing and so fall to the ground. It has been found that lice buried at a depth of four inches will crawl to the surface. They may be blown by wind. Lice are ordinarily not found in bedding and blankets unless recently occupied by vermin infested individuals.

Lice are most often found in those parts of the garment which are in closest contact with the body, such as the fork of the trousers, waistline, armpits and neck. They are found in the inner as well as

<sup>109</sup> *Parasitology*, IX, 228-258, Feb. 26, 1917. *Proc. Royal Soc. Med.*, London, X, 61-94, June, 1917.

<sup>110</sup> Observed by Plotz during typhus fever epidemic in Serbia and Bulgaria, 1915-16.

the outer garments. Lice may be found on any garment or article worn by an infested man. In conducting inspections for lousiness, it is important to remember this, and to bear in mind that the body louse may lay its eggs on the hair of the head as well as any other hairy part of the body. This is of importance, and neglect of it leads to unsatisfactory results. The delousing of clothing alone is not sufficient.

*Pediculus capitis*, or the head louse, is perhaps the commonest variety of louse in civil life. Sobel<sup>111</sup> states that about twenty-two per cent. of the school children in New York are infested, some 150,000 to 185,000 cases being reported during the years 1909 to 1912. *P. capitis* shows no material difference in its biology from the *P. corporis*. It lays fewer eggs and is perhaps shorter lived. It is found mostly in children, especially in girls on account of their long hair, and in old people. It is fond of the temporal and occipital regions. Although the hairy head is the common habitat, still it may be found on other parts of the body, in which case it would be difficult to say whether it was *corporis* or *capitis*. This insect is spread by contact such as occurs in schools, and by brushes and hats. The common clothes-hook in school houses may be a method of transfer. If hair is worn short infestation rarely occurs. It has been reported by Goldberger<sup>112</sup> that the head louse may transfer typhus fever.

An effective treatment is to anoint the head with a mixture of equal parts of kerosene and vinegar or kerosene and olive oil; head to be wrapped in a towel over night and shampooed in the morning. Repetition of this procedure may be necessary. Combing with a fine warm comb will remove the nits. In males the hair should be cut (see page 1347).

*Phthirus pubis*, crab louse.—This insect looks unlike *Pediculi* and closely resembles a crab. It is about one-sixteenth of an inch long. It is usually found in the pubic and perianal region, but may be found over the abdomen and chest, axillae and down over the thighs. Crab lice have been found in the eyebrows. The nit is laid near the base of the hair. *Phthirus* feeds almost continuously, and hence dies rapidly when removed. A female lays about twenty-five eggs in her lifetime. Eggs hatch in about seven days. Development is the same as *Pediculus*. This insect is transmitted mainly by contact in lodging houses, houses of prostitution, bath tubs, and from toilet seats. It has not been known to transmit disease. Treatment consists in shaving. If skin irritation is present apply some bland ointment. The use of blue ointment may cause skin irritation and therefore should not be so commonly employed.

**Lice Bites and Transmission of Disease.**—Lice most likely transmit disease by way of the excreta, the virus gaining entrance through the

<sup>111</sup> N. Y. Med. Journ., XCVIII, 656-664, Oct. 4, 1913.

<sup>112</sup> Public Health Reports, XXVII, 297-307, 1912.

punctured wound made by the louse while feeding, or scratched in by the individual. Mueller and Urizio<sup>113</sup> were able to transmit typhus fever even without the bite of the insect. Mueller himself contracted typhus fever as the result of an accident, in which an emulsion of lice feces spilled on his hands. The period of incubation was 17 days.

The effects of the presence of lice upon men differ according to individual susceptibility. Persons who are constantly vermin infested are immunized against the salivary secretion, and the local reaction of the bites is very slight. Sometimes only a slight puncture wound is discernible. In persons who have never been lousy before, the local reaction is intense and indicated by an urticarial wheal or hemorrhagic spot. Lice bites in themselves may cause a mild febrile reaction and a generalized eruption resembling measles.<sup>114</sup>

**Delousing.**—The best delousing methods should not only destroy lice and their eggs, but also the viruses transmitted by the insect. Fortunately, the viruses of relapsing fever, typhus fever and trench fever are comparatively frail; they are destroyed at 70° C. moist heat for 30 minutes. Lice and nits are killed at this temperature; also at 55° C. dry heat in 5 minutes. It is a comparatively simple matter to kill lice and their nits—only the administrative aspect of the problem presents any real difficulty. The most frequently used methods are heat, chemicals or storage.

*Heat.*—Dry heat is convenient, but not effective in large scale operations because it lacks the power of penetration. Dry heat has the advantage in the case of leather material and rubber goods, which may be thus disinfested without injury. Shoes are rarely infested; in fact, leather and rubber articles as a rule need not be treated except in the presence of heavy infestations or an epidemic. Steam penetrates better, is quicker, surer; and it also disinfects.

Heat may be applied in a great variety of ways:—boiling water, Serbian barrel, steam, flat iron, hot oven, hot air boxes or huts, steam disinfectors.

The *flat iron* was employed in some armies. The method is effective, but impracticable on a large scale as it is time-consuming. If used in connection with a delousing plant, the number of ironers would have to equal the number of bathers so that the clothes would be ready for the men when they came out of the bath. It takes about 15 minutes to iron a uniform and underclothes.

*Hot ovens* have been used. This method may be applied on a small scale. Care must be observed not to scorch the clothing. A very effective hot air method is the hot air hut, described by Captain Orr of the

<sup>113</sup> *Riforma Medica*, Aug. 30, 1919, XXXV, No. 35, p. 734.

<sup>114</sup> Hirschfelder and Moore: *Arch. Int. Med.*, Apr. 5, 1919, XXIV, No. 4, p. 419.

<sup>115</sup> *Parasitology*, Vol. X, No. 4, p. 441, May, 1918.

Canadian Army.<sup>115</sup> The penetration with dry heat is not as complete as when using steam. Stagnant hot air is less effective than circulating hot air. In the front area, in dugouts and trenches, the hot box<sup>116</sup> may be used. This box is based on the principle of the fireless cooker, and used by heating a piece of metal, and placing the clothing, which is protected from coming in contact with the metal, over it. The temperature obtained is sufficient to destroy lice and eggs.

*Hot water.*—Lice and eggs immersed in water at 70° C. for 30

SERBIAN BARREL

FIG. 48.

minutes are killed with certainty—this method is not practical on a large scale.

The *Serbian barrel* is one of the best improvised methods for de-lousing with steam. It was used during the typhus campaign in Serbia and Bulgaria. It consists of a large barrel, the bottom of which is freely perforated, while the top is removed and replaced by a weighted lid. At the lower end is a sand bag collar to prevent the escape of steam, which enters the barrel from a metal boiler upon which it rests. both barrel and boiler being imbedded at their junction in the brick work forming the furnace. The furnace may be made long and narrow,

<sup>115</sup> Devised by Harry Plotz, War Department.

with a chimney at one end, and the boilers and barrels placed in series. It is important that steam be generated rapidly. The clothing to be deloused is placed in at the top and the lid placed on tightly. After the steam is generated, the clothing remains in the barrel for one hour.

All clothing, except leather material, rubber and celluloid, may be handled in this manner. There are various other improvised methods for obtaining steam such as boxes and huts.

*Steam Disinfectors.*—The large commercial steam disinfectors are the best and quickest way of delousing large quantities of clothing. With the aid of the vacuum, penetration is sure and the materials are both disinfested and disinfected. Steam may also be used in improvised methods in a freight car, obtaining the steam from the locomotive; or in the compartments of a ship.

The *steam laundry* is a good delousing apparatus, provided live steam is run into the wash wheel. It takes about 15 minutes to insure a proper temperature.

Clothing can be freed of lice by *storage*. Sufficient length of time must elapse for the adult lice to die and nits to hatch. Nuttall<sup>117</sup> advises clothing stored in a dry temperature for two to three weeks. Since hatching has been delayed thirty-five days by low temperature, it would be safe to allow thirty to forty days during cool weather.

*Chemicals* are used for two purposes; to destroy lice and nits on clothing and hair, or to repel them. Numerous licides have been recommended, but experience has shown most of them to be worthless; they may destroy lice, but rarely do they destroy nits.

The most effective insecticides for louse control are kerosene, naphthalene, carbonbisulphid and lysol. The English employed the N. C. I. powder with some success. This consists of

Naphthalene .....	96 per cent.
Creosote .....	2 per cent.
Iodoform .....	2 per cent.

The commercial naphthalene is the best. This powder acts as a repellent; therefore it should be dusted into the clothing frequently—every three days. The best results are obtained by dusting the seams of the clothing freely and then rolling in a blanket. Care must be exercised in using the powder in the fork of the trousers, as it may cause smarting. Some observers have had just as good results with crude naphthalene. A powder consisting of talc, 20 gms., creosote, 1 c. c., sulphur, 0.5 gms., has been suggested by Moore,<sup>118</sup> and is supposed to be effective. It causes less irritation to the skin than the N. C. I. powder.

<sup>117</sup> *Parasitology*, IX, pp. 293-294; X, No. 1, Nov., 1917; X, No. 4, May, 1918; X, pp. 375-382; X, pp. 383-405.

<sup>118</sup> *Journ. Lab. and Clin. Med.*, III, 1917-18, p. 261.

In conjunction with the N. C. I. powder, the English use a mixture known as Vermijelli, which consists of:

Crude mineral oil.....	5½ pints.
Soft soap .....	3 lbs.
Water .....	About ½ pint.

This is smeared in the interior seams of the clothing. Impregnation of underclothing with various chemicals has given unsatisfactory results. Sachets are only effective for a short time.

Various *fumigation methods* have been recommended, but experience has shown that most of the gases do not destroy nits. The value of sulphur and formaldehyd has been overestimated. Nits are not destroyed. The use of hydrocyanic acid gas has been recommended, and it was found that 3 ounces to 3½ ounces per 100 cubic feet would be sufficient to kill adult lice and to prevent eggs from hatching, when the surface of the clothes are freely exposed to the fumes for one-half hour. When clothes are tightly packed in trunks, 6 ounces per 100 cubic feet with 25 inch vacuum should be used for two hours in special apparatus. As this gas is very dangerous, it should not be employed in camps. It does not destroy bacteria. Chlorpicrin has been recommended by Moore,<sup>119</sup> who states that it penetrates clothing and is said to kill lice and eggs. He uses 4 c. c. to 1 cubic foot for 30 minutes.

**Lice as a Military Problem.**—The control of vermin infestation and louse-borne diseases was one of the important sanitary and medical problems of the World War. As an army problem, the unprecedented scale of the war, combined with the conditions under which it was fought, led to a prevalence of lice among soldiers that has never been equaled before. No army was spared from widespread vermin infestation, and diseases transmitted by this pest. The louse not only transmits typhus fever, trench fever and relapsing fever, but its presence disturbs the morale of the soldier by causing irritation of the skin and scratching, often followed by infection, loss of sleep and impaired efficiency. The loss of life from typhus fever in Serbia and Roumania was enormous, and the non-effective rate from trench fever was so high as to cause serious concern.

Vermin infestation in our army was prevalent. It is said that practically every man that reached the front area became infested. Any large assemblage of soldiers is likely to contain a few verminous individuals, who are primarily the cause of the trouble, which is greatly aggravated by the crowding and camp conditions.

The method of excluding vermin infestation and louse-borne disease by returning troops was handled in the following manner:<sup>120</sup> All

<sup>119</sup> *Journ. Lab. and Clin. Med.*, III, 1917-18, p. 261.

<sup>120</sup> War Department Order.

troops were detained for two weeks at foreign ports before boarding a transport, during which time contagious disease was isolated and delousing was practiced. All troops were again examined on transports as soon after departure as possible, and reëxamined again after six days. During the intervening time, each soldier was instructed to examine his clothing daily for vermin. On arrival in the United States, civilians were carefully kept from coming in contact with soldiers. All soldiers were sent to the nearest camp, where delousing was again practiced. An area was set aside for the receipt of "unclean" troops, and following delousing they were placed in a clean area. Up to July, 1919, about 2,000,000 troops were returned to the United States, and not a single case of a louse-borne disease was introduced into this country, and vermin infestation was not carried into civil communities by demobilized soldiers.

The delousing plant <sup>120a</sup> devised by Major Harry Plotz is shown in Figure 49. It can handle 200 soldiers and their equipment an hour. The U. S. Public Health Service also has efficient plants at its maritime quarantine stations, and traveling railroad equipment for work on the Mexican border.

### TYPHUS FEVER

(*Typhus Exanthematicus*)

Typhus fever was formerly confused with typhoid fever. Louis in 1829 named typhoid fever, but it remained for one of his pupils, Gerhard, clearly to lay down the difference between the two diseases. Previous to that time, typhus fever was prominent and prevailing, while typhoid fever was unknown as such and probably did not occur in great epidemics. Up to the time of the World War, the situation was reversed; typhoid fever had become pandemic, while typhus fever had receded with civilization and improvements in sanitation. Since the beginning of the World War, epidemics of typhus fever have occurred in Serbia, Bulgaria, Turkey, Russia, Poland, Germany and Mexico. The history of this disease has been repeated again. War followed by poverty and distress associated with vermin infestation favors the spread of typhus fever.

Typhus fever is a disease of cool and temperate climate, and is found in Europe, Asia, Africa and America, the most common foci being Russia and the Balkans, Ireland, Poland, Galicia, Spain, Italy and Mexico. In ten years, 1871-80, in Ireland 7,495 deaths were reported from typhus fever; in three years, 1909-11, the number had fallen to 143. It is reported that Serbia lost 150,000 people from this disease alone, during the winter of 1915-16.

<sup>120a</sup> The details of construction and operation are described in *J. A. M. A.*, Feb. 1, 1919, Vol. LXXII, p. 324.

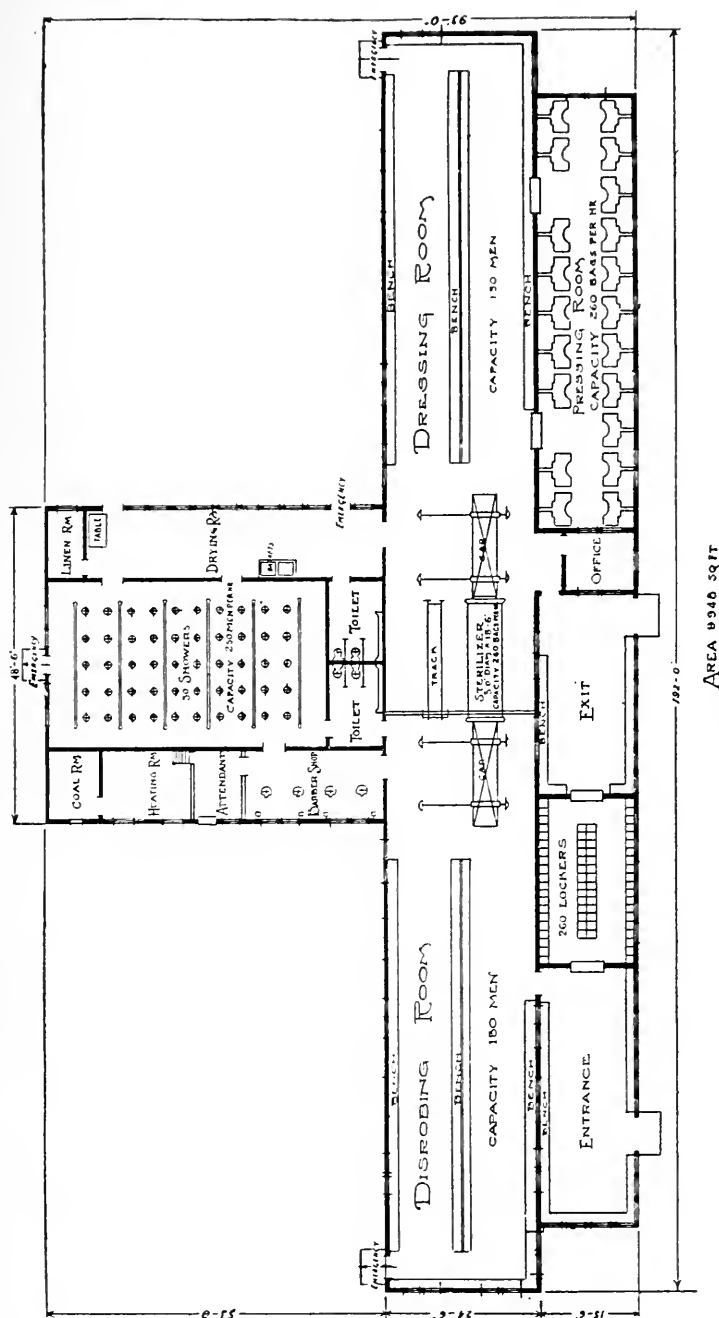

FIG. 49.—DELOUSING PLANT.

Typhus fever prevailed in epidemic form in the United States in New York in 1881-1882, and again in 1892-1893, and in Philadelphia in 1883. Since then, except for a few sporadic cases at our seaports, the disease has been thought to be non-existent in the United States. However, Anderson and Goldberger have shown the close relationship between the symptom complex known as "Brill's Disease" and typhus fever, and believe that European typhus fever and the typhus fever or "tabardillo" of Mexico are the same disease. It is now evident that typhus fever has been smoldering in New York a great many years, certainly since 1896, when Brill first observed the cases which he described. The disease in New York is generally mild. It is believed that some cases are not diagnosed; therefore, we face a new sanitary problem in this country. Typhus fever in virulent form is now (1921) being reintroduced into the United States with the tide of immigration from epidemic centers.

Typhus fever, when prevalent in epidemic form, has been said by the older writers to be one of the most highly contagious of febrile diseases; doctors and nurses and others in close contact with the disease being almost invariably stricken. Typhus fever claims more victims in the medical profession than any other epidemic disease. The loss of life of physicians in Serbia and Bulgaria was particularly high. The sad case of Ricketts, who lost his life in endeavoring to unravel this pathologic puzzle in Mexico, is still fresh in our minds. Others who have sacrificed their lives in studying this disease are Donnelly and Macgruder in Serbia, Husk in Mexico, and Jochmann and Prowazek in Germany.

The period of incubation is from five to twenty days, with an average of twelve. Typhus epidemics prevail during cold weather—the disease dies down in summer, probably due to the fact that heat renders lice sluggish. One attack confers a very definite immunity, second attacks being very unusual.

**Etiology—Rickettsia.**—*Rickettsia* are small, bacteria-like bodies, probably belonging to the protozoa. They stain with difficulty; best with Geimsa or one of the modifications of Romanowski's stain. *Rickettsia* occur in pairs and clusters within the cells in typhus and Rocky Mountain spotted fever and without the cells in trench fever. They are small—a pair measures about one micron long. They do not grow in artificial culture media. They are frail and easily killed. *Rickettsia* appear to be a group of microorganisms especially adapted to insect life. Some representatives of the group are pathogenic for man and animals.

*Rickettsia prowazeki* is now believed to be the cause of typhus fever. It was named by da Rocha Lima <sup>121</sup> in memory of Ricketts and Prowa-

<sup>121</sup> *Deutsch. med. Woch.*, July 3, 1919, p. 732.

zek, both of whom succumbed to typhus while investigating the disease.

*Rickettsia prowazeki* found in typhus fever and Rocky Mountain spotted fever differs from *Rickettsia pediculi*, associated with trench fever, in that the former is found especially in the epithelial cells of the alimentary canal of the louse, while the latter occurs only in the lumen of the alimentary canal, and not in the cells of the louse.

Wolbach<sup>122</sup> states that the pathology of typhus fever consists largely of lesions of the blood vessels. There is disintegration of the endothelium and proliferation causing thrombi and hemorrhages, also perivascular infiltration with cells. These lesions in the brain account for the delirium and other mental symptoms which are prominent in typhus fever. Similar lesions of the blood vessels of the skin produce the macular and hemorrhagic eruption. The thrombi give rise to gangrene which is often symmetrical.

**The Weil-Felix Reaction.**—The blood of typhus fever patients agglutinates a proteus-like organism, and this reaction is specific and diagnostic, despite the fact that the proteus-like bacillus is not the cause of typhus fever.<sup>123</sup> This reaction appears to be due to the fact that typhus fever blood contains non-specific agglutinins, for it will not only actively clump the proteus-like bacilli, but also typhoid, dysentery and many other bacilli.

The disease may be transmitted by blood inoculations to man, chimpanzees, lower monkeys and guinea-pigs. The reaction in animals is quite typical, characterized by an incubation period which varies from 7 to 10 days in guinea-pigs, and rise of temperature from 7 to 11 days, usually ending by crisis. An animal that has gone through such a reaction is immune. A large percentage of guinea-pigs is immune to the first blood inoculation and many are naturally immune. The virus as it exists in the circulating blood does not pass through a Berkefeld filter. It is not killed by freezing for 8 days, but is deprived of virulence by heating at 55° C. for 15 minutes.

**Transmission.**—Tobias Coberus, in the beginning of the 17th century, associated the louse with typhus fever, but Nicolle, Compte and Conseil, in 1909, were the first to report the transmission of typhus fever by the bite of the louse (*Ped. vestimenti*). Their work was suggested by the successful transmission of relapsing fever through lice, by Sergeant. Since the work of Nicolle and his collaborators, his work has been confirmed by Ricketts and Wilder, Anderson and Goldberger, and others. Goldberger has shown that the head louse (*Ped. capitis*) may also transmit this infection. The period of infectivity in lice, following exposure on typhus patients, is reported to vary from 2 to 10 days

<sup>122</sup> *International Jour. of Public Health*, Sept., 1920, I, No. 2; *Journ. Med. Res.*, Nov., 1919, p. 197; *Journ. Inf. Dis.*, July, 1915, p. 1.

<sup>123</sup> *Wien. klin. Wochenschr.*, XXIX, No. 2, 1916.

by different observers. Rickettsia bodies have been found in the stomach wall of typhus infected lice by Prowazek, da Rocha Lima, Wolbach and others.

The feces of typhus-infected lice are infective for animals. There is a difference of opinion as to the method of transmission of typhus fever by the louse; that is, whether it occurs by the bite or through the excreta. The disease is most likely introduced through the feces, the virus gaining entrance through the punctured wound made by the louse while sucking, or scratched in by the host.

The rôle of the body louse in the transmission of typhus fever will receive ready support from students of the epidemiology of typhus fever, for this disease presents all the characteristics of an insect-borne disease. In practice, the control of lice has greatly reduced the incidence of the disease. Since the transmission of the disease by the louse has been shown, we can understand why typhus fever prevails in epidemic form only in overcrowded, filthy, unhygienic surroundings, and the truth is readily understood of the oft quoted sentence of Hirsch that "the history of typhus is the history of human wretchedness."

**Prevention.**—The disease has been greatly decreased in civilized centers with a diminution of lousiness. The prevention of typhus now focuses itself upon the eradication of the body louse—a question of personal cleanliness. Typhus fever is also a social problem in that it is so closely interwoven with squalor, ignorance and poverty. Measures primarily directed to the destruction of lice and their eggs are described on page 366.

In the presence of a typhus epidemic, a separate typhus hospital should be established and a separate building or enclosure for typhus contacts. When a case of typhus fever is discovered, the patient should be removed to the typhus fever hospital, never treated at home. All the clothing should be removed in the receiving ward, and all articles of apparel taken away. This material should be disinfected by steam and placed in a storeroom; never allowed to be taken into the ward. The hair of the head, axillary and pubic region should be cut with a hair clipper. The hair should be carefully collected and burned. The patient is then bathed, using warm water and a kerosene soap mixture. Patients can be rapidly handled if the receiving department is divided into a receiving room, barber shop, bath room, drying room, and examining room. The patient is given clean pajamas in the examining room and then sent to the ward. Stress is laid on this procedure of admitting patients, in order to prevent lice from getting into the ward.

Daily vermin examinations are made on the patients and in the bedding. Lice wander from the host during fever; hence they may be found in the bedding. This, no doubt, accounts for the high incidence among physicians and nurses. All attendants in the wards and all

nurses and doctors should wear louse-proof suits. This is a garment made of heavy muslin, like pajamas, which goes over and covers the shoes and is tied about the neck. A hood may be attached. Cotton gloves are sewed in the sleeves by machine stitching. Nurses should wear the same garment with a skirt. A sterilized garment should be put on each time the attendant, doctor or nurse enters the ward. On leaving the ward, the garment is removed by an attendant, preferably a typhus immune, placed in a bag and steamed. A shower room and clothes closet should be provided near the exit of the ward, where nurses may change their costume. Under no circumstances should visitors be allowed into the ward. In typhus-stricken countries, one must be extremely cautious of the attendants. As these people usually come from the peasant class, where the epidemic prevails, their habits of cleanliness are usually very primitive. They must be taught the value of cleanliness, supplied with proper living quarters and repeatedly inspected for vermin. They should be isolated during the epidemic. It is preferable to have typhus immunes as attendants in the hospital.

The room from which the patient is removed should be fumigated with sulphur, or, better, hydrocyanic acid gas, and cleaned with kerosene, and should then be closed for two weeks if possible. A portable steam disinfector is useful to disinfest and disinfect fabrics, etc., in a typhus campaign. Carriages and wagons which carry patients to the hospital should be carefully inspected for lice and cleaned. If patients are removed on trains, the cars should be cleaned by vacuum cleaner and washed. During an epidemic, all plush on railway cars should be removed; abroad only freight cars or third-class cars are employed.

All contacts should be isolated for fourteen days at least; twenty-one days would be better, in a separate building or camp, being carefully deloused before entering. They should be directed to examine their clothing daily for lice and should be inspected for vermin by medical officers daily. Their temperature should be taken twice daily and daily inspections made for the first symptoms of the disease.

An educational campaign should be carried on in the cities by lectures in public places and schools, pamphlets, sermons and moving pictures. As typhus fever is usually associated with ignorance, poverty and distress, sanitary instructions as well as proper clothing and food should be supplied the stricken people.

The fact should be kept constantly in mind that the louse is necessary for the spread of typhus fever, just as the mosquito is for the spread of malaria, and our efforts towards prophylaxis should be conducted with this point continuously in mind. Even with the knowledge of the mode of transmission of typhus fever, individual prophylaxis is still somewhat difficult, especially where infected insects abound in thickly populated centers.

## TRENCH FEVER

Trench fever is a specific infection due to a filterable virus transmitted by the louse *Pediculus humanus*, var. *corporis*. The disease is characterized in its early febrile stage by recurrent pyrexia, headache, giddiness, a slow pulse in comparison to the degree of fever, sweating, polyuria, and a moderate leukocytosis at the height of the fever. Trench fever is never fatal, and complete recovery usually takes place. A certain percentage of the patients, however, pass into a stage of chronic ill health; that is, they suffer with recurrent pains in the limbs, headache and nervous manifestations, such as mental depression, excessive tendency to sweating, disordered action of the heart, mild degree of anemia, and some loss of weight. The infection in some cases is very persistent, and acute febrile relapses may occur after months of quiescence.

The Trench Fever Commission of the American Red Cross<sup>124</sup> concluded, as a result of extensive researches as follows:

1. Trench fever is a specific infectious disease; it is not a modified form of typhoid or paratyphoid fever, and is not related, from an etiological standpoint, to these diseases.

2. The organism causing the disease is a resistant filterable virus.

3. The virus causing trench fever is present particularly in the plasma of the blood of trench fever cases, and such plasma will produce the disease on inoculation into healthy individuals.

4. The disease is transmitted naturally by the louse *Pediculus humanus*, Linn., var. *corporis*, and this is the important and common means of transmission. The louse may transmit the disease by its bite alone, the usual manner of infection, or the disease may be produced artificially by scarifying the skin and rubbing in a small amount of the infected louse excrement.

5. A man may be entirely free from lice at the time he develops trench fever, the louse that infected him having left him some time previously as its host, and the louse need only remain upon the individual for a short period of time in order to infect him.

6. The virus of trench fever is also sometimes present in the urine of trench fever cases, and occasionally in the sputum, and the disease may be produced in man by the introduction of the virus in the urine or sputum through the scarified or otherwise abraded skin.

7. Since the urine and sometimes the sputum of trench fever patients

<sup>124</sup> Trench Fever. Report of Commission, Medical Research Committee, American Red Cross: Major Richard P. Strong, Major Homer Swift, Major Eugene L. Opie, Captain Ward J. MacNeal, Captain Walter Baetjer, Captain A. M. Pappenheimer, Captain A. D. Peacock, and Lieutenant David Rappoport. Oxford Univ. Press, 1918.

are infective, these should be sterilized in order to avoid the possibility of accidental infection from them.

8. In order to prevent trench fever or limit its spread, and thus save man-power for the armies, greater efforts must be made to keep soldiers in general from infestation with lice.

The method of transmission of trench fever was still further elucidated by the work of Byam and his associates on the British Trench Fever Commission.<sup>125</sup> They found that biting by infected lice was not of itself sufficient to transmit the disease, but that the excreta of such lice, rubbed into the scarified skin, would do so with great regularity. The excreta were found to be infective only after an interval of seven days or more after feeding on the trench fever patient; this fact suggests the possibility that the organism undergoes a developmental cycle within the louse. Lice were found to remain infective for a period of at least twenty-three days after feeding on the patients. These experiments indicate that infection in nature probably occurs by rubbing in the louse excreta in the process of scratching.

The cause of trench fever is believed to be *Rickettsia pediculi*, which are described on page 373. The lesions of the disease are largely vascular, similar to those described for typhus fever and Rocky Mountain spotted fever.

Trench fever is a war disease. While it is not fatal, the morbidity resulting from it exceeded that from any other disease on the western front in the World War. No epidemics of the disease have been reported in civil life.

The prevention of trench fever resolves itself primarily upon an attack against lice. In addition, urine, sputum and other secretions are infective and disinfection must be practiced. The Red Cross Commission recommends the following measures:

Exceedingly great care should be taken completely to disinfect all patients as soon as practicable, and particularly upon their entering the hospital. Patients on entrance should be carefully bathed, and subsequently sponged with alcohol. Their clothing and blankets should be removed, and, whether or not lice or ova are found upon them, should be carefully sterilized by moist heat at a temperature not below 70° C. for half an hour, since it is possible for the virus to be still present on the clothing. It should be borne in mind that a man with trench fever may be entirely free from lice at the time that he develops symptoms of the disease. Trench fever patients should at all times be carefully protected from louse infestation, and inspection of them for lice should be made daily. They should be treated in separate wards. As the urine contains the virus and is infective, it should be sterilized during the active stages of the disease. Sputum cups should be provided for

<sup>125</sup> *Jour. A. M. A.*, LXXI, pp. 21, 110, 188, 1918.

patients, and any expectorated sputum and saliva from them sterilized. Officers should regard the systematic destruction of lice as one of the most urgent of their duties, and should exercise every effort to prevent louse infestation among soldiers and to see that any of them infested with lice are promptly disinfected and their clothing sterilized. The above precautions are of the utmost importance in order to prevent the further spread of trench fever among troops.

## BEDBUGS

*Cimex lectularius* has been carried by man to all parts of the inhabited world. It has become a true domesticated animal and has accommodated itself well to the environment of human habitations. The bedbug has no wings and a very flat body, which enables it to hide in the narrowest chinks and cracks of beds and walls. It may subsist for incredibly long periods of time without food. It is nocturnal in its habits.

The pronounced odor of this insect is produced by certain glands opening on the back of the abdomen in young bugs and on the under side of the metasternum in the adults. The odor is common to most members of the group to which this insect belongs. It is useful in plant bugs, protecting them from their enemies.

The bedbug<sup>126</sup> undergoes an incomplete metamorphosis, the young being very similar to their parents in appearance, structure, and habits. The eggs are white, oval objects having a little projecting rim around one edge, and are laid in batches of from six to fifty, in cracks and crevices where the bugs go for concealment. The eggs hatch in a week or ten days and the young escape by pushing the lid within the projecting rim from the shell. At first the larvae are yellowish-white, nearly transparent, the brown color of the more mature insect increasing with the later molts. During the course of development the skin is shed five times, and with the last molt the minute wing pads, characteristic of the adult insect, make their appearance. Marlatt found that under favorable conditions about seven weeks elapse from the egg to the adult insect, and that the time between molts averages about eight days. Without food they may remain unchanged for an indefinite time. Ordinarily but one meal is taken between molts, so that each bedbug must puncture its host five times before becoming mature, and at least once afterward before it can develop eggs.

The presence of bedbugs in a house is not necessarily an indication of neglect or carelessness. They are very apt to get into trunks and satchels of travelers or may be introduced in the homes upon the cloth-

<sup>126</sup> The Bedbug, *U. S. Public Health Rpts.*, Dec. 10, 1920, p. 2964.

ing of servants, workmen, or visitors. The bedbug is quite capable of migrating from one house to another. Ships are almost sure to be infested with them. They are not especially limited by cold, and are known to occur well north. They thrive particularly in old houses which are full of cracks and crevices, in which they can conceal themselves beyond easy reach. The biting organ of the bedbug is similar to that of other hemipterous insects. The skin of the host or victim is pierced with four thread-like hard filaments or setae, which glide over each other with an alternating motion and thus pierce the skin. The blood is drawn up through the beak, which is closely applied to the point of puncture. The bite of the bedbug is decidedly irritating to

FIG. 50.—THE BEDBUG.

*a*, Adult female, gorged with blood; *b*, Same from below; *c*, Rudimentary wing pad; *d*, Mouth parts. After Marlatt.

some individuals, resulting in a swelling and disagreeable inflammation.

**The Suppression of Bedbugs.**—On account of its habits of concealment the bedbug is usually beyond the reach of the ordinary insect powders, which are practically of no avail against it. If iron or brass bedsteads are used, the eradication of the insect is made easier. Large wooden bedsteads furnish many cracks and crevices into which the bugs can force their flat thin bodies, and extermination becomes a matter of considerable difficulty. The most practical way of eradicating bedbugs is by a very liberal application of gasoline, benzene, kerosene, or any other of the petroleum oils. These must be introduced into all crevices with small brushes or feathers, or by injecting with small syringes; a saturated solution of corrosive sublimate in water is also of value, and oil of turpentine may be used in the same way. The liberal use of scalding hot water or soap suds wherever it may be employed without damage to furniture is also an effectual method of destroying both eggs and active

bugs. Fumigation with hydrocyanic acid gas, sulphur dioxide, or carbon bisulphid are alike effective. Several fumigations may be necessary. Crevices in warm parts of the room are favorite nesting places, as under picture moldings, or over door frames. Finally, the room should be renovated, all imperfections and cracks closed and sealed with paint.

In sleeping cars and other places where hydrocyanic gas may be used without fear of accidents, this is the most efficacious and least destructive method.

The bedbug has long been under suspicion as an intermediate host in the transference of many communicable infections. There is more than a suspicion that it is concerned in relapsing fever, in kala-azar, and it has been accused of carrying the bacteria of plague, leprosy, and many other diseases. On the other hand, there is no convincing evidence that the bedbug is the usual and ordinary insect transmitter of these or any other disease at present known to us. When the bedbug acts as an intermediate host, it apparently does so by mechanical transmission of the virus on the mouth parts—and this occurs only under grossly unsanitary conditions. Notwithstanding the minor rôle which must be assigned the bedbug as a carrier of disease, its presence is an offense against sanitary decency.

### LEISHMANIASIS

(*Kala-Azar*, "*Dum-Dum Fever*," *Oriental Sore*, *Etc.*)

Leishmaniasis <sup>127</sup> is a specific infection caused by a minute flagellated animal parasite. The disease usually runs a chronic course and is characterized by irregular fever, enlargement of the spleen and anemia. It is found in most tropical countries, but is unevenly distributed. It occurs as slowly progressing epidemics, and also is endemic in parts of India, China, northern Africa, and South America. There are three clinical forms:

(1) *Indian kala-azar* (splenic anemia) is a chronic disease characterized by a very large spleen, irregular fever and anemia; it occurs at all ages. It is caused by *Leishmania donovani*.

(2) *Mediterranean kala-azar* usually occurs in children under the age of five or six years. This form is found around the Mediterranean basin and is characterized by the severity of the associated anemia. It is caused by *Leishmania infantum*.

Laveran believes that the so-called Indian and Mediterranean forms of the disease are identical. This view, however, is not shared by other authorities. Both these forms are generalized infections and had a high mortality (70 to 98 per cent.) before the use of tartar emetic.

<sup>127</sup> Laveran, A.: Leishmaniasis. Kala-Azar. Bouton D'Orient. Leishmaniose Americaine. Pub. Masson et Cie., Paris, 1917.

(3) *Oriental sore* occurs throughout the tropical belt and passes under many names, such as, Tropical ulcer, Delhi boil, Aleppo boil, Biskra button, and Espundia. Oriental sore usually occurs upon the exposed surface of the body and starts as a papule, which subsequently ulcerates. The ulcer persists for months or years, finally healing spontaneously. It is thus a local and self-limited form of leishmaniasis. The parasite (*Leishmania tropica*) is found in great numbers in the ulcer, but apparently never becomes disseminated throughout the body. In South America a form of leishmaniasis (Espundia) occurs, which often extends to the mucous membrane of the nose and palate, causing extensive destruction of tissue with serious deformity.

The parasite, for a time commonly known as the Leishman-Donovan body, is found chiefly in the endothelial cells of the liver, spleen, bone marrow and lymphatic glands. It is of rounded or ovoid form, and contains two deeply stained granules representing nuclei. This body represents the non-motile phase of the life cycle of a flagellate. It was first demonstrated by Leishman<sup>128</sup> in 1900, from a case of "Dum-dum fever." Donovan<sup>129</sup> in 1903, found similar bodies in cases in Madras. James Homer Wright<sup>130</sup> was the first to demonstrate the parasite in a case of Oriental sore, at the Massachusetts General Hospital, in Boston. The nature of these parasites was not understood until Rogers<sup>131</sup> succeeded in 1904, in cultivating them in citrated blood and showed them to be flagellated. Later on, Novy's method<sup>132</sup> for the cultivation of trypanosomes was found to be especially useful. On Novy's medium, the parasite increases in size, develops a single flagellum, and becomes actively motile. The medium known as N. N. N. (Novy-Mac Neal-Nicollé) is the easiest to prepare and gives the best results. It consists of agar (16 grams), NaCl (6 grams), and water (9,000 c. c.), which is distributed in tubes, sterilized and cooled to 40°-50° C., when one-third its volume of rabbit blood obtained by cardiac puncture is added.

No marked differences have been discovered between the three "species" of *Leishmania* in morphologic or cultural characteristics. Immune reactions are feeble or wanting, which corresponds to the action of other animal parasites. A certain degree of immunity is present. Thus, Jewish physicians in Bagdad have long practiced inoculation of the virus upon the leg in order to prevent disfigurement of the face.

The period of incubation is irregular, and somewhat uncertain; in Oriental sore it may be months.

The precise mode of transmission of leishmaniasis is still in doubt.

<sup>132</sup> Contribution to *Medical Research*, dedicated to V. C. Vaughan, Ann Arbor, Michigan, 1903, p. 549.

The disease is limited to man, except that it occurs naturally in dogs, especially in the region of the Mediterranean. It may be transmitted experimentally to monkeys, dogs and mice. The disease can be reproduced in man and animals by inoculation of pure cultures, or tissue containing the parasites. It has long been observed that in regions where it is endemic, Oriental sore may follow injury to the skin, however slight, such as abrasions or insect bites.

Leishmaniasis is probably an insect-borne disease, although wound infection doubtless also occurs. Experiments designed to transmit the disease by blood-sucking insects have thus far proved unsuccessful. The development of the parasite has been observed in various blood-sucking arthropods. Patton<sup>133</sup> suspects the bedbug as the transmitter and finds that *Leishmania donovani* can develop into the flagellate stage in the digestive tract of the bedbug, although it survives for only a short time in this host. Temporary development has also been found to occur in mosquitoes, but no development whatever takes place in lice or fleas. It is a difficult problem to differentiate the developing forms of *Leishmania donovani* from herpetomonads which naturally occur in these insects.

A great advance in the treatment and prevention of leishmaniasis was made when it was discovered that tartar emetic and other compounds of antimony are specific for all forms of the infection. Vianna<sup>134</sup> in 1913, reported the effects of tartar emetic upon the disease occurring in Brazil. This was soon confirmed by Castellani,<sup>135</sup> 1914, and many others. Rogers employs intravenous injections of a 2 per cent. solution of tartar emetic. The first dose is 2 c. c. (for adults) which is increased up to 10 c. c. every two days, until symptoms appear, such as nausea and epigastric pains.

The prevention of leishmaniasis consists first in early diagnosis and specific treatment. Such measures generally applied would greatly decrease the amount of the infection and its liability to spread. A warfare against bedbugs, mosquitoes and other biting insects must be carried on, for even if some insect is not the intermediate host, the wound produced from a bite may be the point of entrance of the parasite which is very prevalent in the endemic centers. All wounds, however trivial, should be promptly treated and adequately protected.

It must be remembered that dogs around the Mediterranean basin have the infection and it is possible that children may contract the disease from them.

The parasites abound in the ulcers of the skin and intestinal mucosa,

from which they may be discharged in great numbers. Infection through various forms of contact, direct and indirect, must be considered and guarded against. Instances are recorded in which Oriental sore has been transmitted indirectly through the use of a towel and other objects.

### ROACHES

Roaches are among the commonest and most offensive of the insects which frequent human habitations. They are under suspicion of conveying several infections. There are no less than a thousand species of the family *Blattidae*. Four of these have become domesticated and cosmopolitan. They are *Periplaneta americana*, *Periplaneta australasiae*, *Blatta orientalis* and *Blatta germanica*.

The main difference between *Periplaneta americana* and *Periplaneta australasiae* is that the Australian roach differs strikingly in the brighter and more definitely limited yellow band on the prothorax, and in the yellow dash on the side of the wings.

*Blatta orientalis* or black beetle, is the common European and English species. The female is nearly wingless in the adult state. *Blatta germanica*, the German roach, has become world-wide in distribution: in this country it is styled the Croton bug. It is now the commonest and best known of the domestic roaches. It is light brown in color, and characteristically marked on the thorax with two dark brown stripes. It is the smallest of the domestic roaches, and multiplies more rapidly than any of them. It is also more active and wary than the larger species, and more difficult to eradicate.

*Structure and Habits.*—Roaches are smooth, slippery insects, in shape broad and flattened. The head is bent downward so that the mouth parts are directed backward, and the eyes directly downward, conforming to their groveling habits. The antennae are very long and slender, often having upward of 100 joints. The males usually have two pair of wings. In some species, as the Croton bug, the females are nearly wingless. The legs are long and powerful, and armed with numerous strong bristles or spines. The mouth parts are well developed and have strong biting jaws like those of a grasshopper, enabling these insects to eat all sorts of substances.

House roaches are particularly abundant in pantries, kitchens, bakeries, and other warm places. They are nocturnal in habits. Their numbers are often not realized unless they are surprised in their midnight feasts. Domestic roaches are practically omnivorous, feeding on almost any dead animal matter, cereal products and food materials of all sorts. They are believed to be cannibalistic. They eat or gnaw woolens, leather, and frequently damage the cloth and leather bindings of books. They soil everything with which they come in contact, leaving

a nauseous, roachy odor. Food so tainted is beyond redemption. This odor comes partly from the excrement, but chiefly from a dark-colored fluid exuded from the mouth of the insect, and also in part from the scent glands. Occasionally they migrate, which accounts for the way in which new houses frequently become suddenly overrun with these vermin.

The eggs are brought together within the abdomen of the mother into an egg capsule, which is a hard, horny pod. It is retained in this position sometimes for weeks, or until the young larvae are ready to emerge. The young are very much like the adults, except in point of size, and in lacking wings. They pass through a number of molts, sometimes as many as seven. The development of the roach is slow, and probably under the most favorable conditions rarely more than one generation per year is produced. The abundance of roaches is therefore apparently not accounted for so much by their rapidity of multiplication as by their unusual ability to preserve themselves from ordinary means of destruction, and by the scarcity of natural enemies.

Natural enemies of the roach are mice, rats, guinea-fowl, tree-frog, ichneumon fly, and other insectivorous animals.

The warfare against roaches consists of: (1) cleanliness; (2) elimination of breeding and hiding places; (3) fumigation; (4) poisons; (5) traps; (6) natural enemies. Scrupulous cleanliness and the keeping of food in jars or places inaccessible to the roach is of prime importance. All unnecessary corners, cracks and imperfections in the structure of the building that favor breeding and hiding places must be eliminated. Roaches may be killed with hydrocyanic acid gas, and also with sulphur dioxid—several fumigations are sometimes necessary. The best poison for roaches is sodium fluorid. This substance very finely ground and mixed with meal of some sort forms the basis of most roach powders found upon the market. The powder should be liberally dusted in all corners, drawers, closets and runways. Sodium fluorid is only toxic to insects when taken internally; it is ineffective against bedbugs probably because that insect cannot be induced to eat it. Other poisons sometimes used are: pyrethrum powder, flowers of sulphur, phosphorus paste, containing 1 or 2 per cent. of phosphorus in sweetened flour. Plaster-of-Paris, 1 part, flour 3 or 4 parts, may be set near a convenient flat plate containing pure water. The insects eat the mixture, become thirsty and drink, when the plaster-of-Paris sets and clogs the intestines. Many roaches may be trapped in a deep, smooth basin or jar. Sticks leading up to the rim of the trap make runways for the insects, which slip into the trap but cannot get out. The best bait for these traps is stale beer. The Croton bug is too wise to be thus trapped.

The roach has been shown by Fibiger<sup>136</sup> to become infested with a

<sup>136</sup> Fibiger, J.: *Berliner klin. Wochenschr.*, Feb. 17, 1913, L, No. 7, pp. 289-332.

round worm. When these infested roaches are eaten by rats, a cancerous-like growth develops in the stomachs of the rats, apparently due to the irritating presence of these worms. Herms and Nelson<sup>137</sup> and also Longfellow<sup>138</sup> have shown the possibility of the conveyance of typhoid and other infections by means of the roach. When we consider that house roaches feed upon all kinds of breadstuffs, milk and its products, meat, clothing, cooked and raw food; that they migrate from one apartment to another, following water and drain pipes, from cellar and sick room to living rooms and bedrooms; that they infest kitchens, store rooms and toilets, opportunity is evidently offered to drag infection mechanically from one place to another. Roaches must therefore be regarded as a sanitary menace.

**References.**—The literature upon insects and insect-borne diseases is very widely distributed. Many of the entomological facts contained in this chapter have been taken from "The Insect Book" by L. O. Howard and the many excellent publications of Howard and his colleagues of the Bureau of Entomology, Department of Agriculture. The Government publications may be had upon application to the Superintendent of Documents, Washington, D. C. Many of the facts concerning the prevention and destruction of mosquitoes have been taken from articles in the *Public Health Reports* of the Public Health Service. In the chapter upon insecticides free reference has been made to my own book upon "Disinfection and Disinfectants," as well as to my other writings and unpublished work in different phases of this subject. Other references are cited in the text. See also:

## CHAPTER V

### MISCELLANEOUS DISEASES

#### INFANTILE PARALYSIS

(*Acute Anterior Poliomyelitis*)

Infantile paralysis is an acute generalized infection, due to a filterable virus, occurring both in epidemic and sporadic form. The virus attacks the nervous system, with a special tendency to localization in the anterior horns of the gray matter of the spinal cord, hence the name anterior poliomyelitis.

Infantile paralysis is often called the Heine-Medin disease, from the fact that Heine<sup>1</sup> of Connstadt, in 1840, first established the disease as a clinical entity, and Medin,<sup>2</sup> a Swedish physician, in 1890, was the first carefully to study an epidemic and to recognize various clinical types, as the cerebral, bulbar, polyneuritic and ataxic forms of the disease. Bergenholz, in 1881, described an outbreak of eighteen cases in Sweden with sufficient accuracy to establish the epidemic form of the disease. The first outbreak described in the United States was reported by Caverley,<sup>3</sup> in 1896, in Vermont. Wickman,<sup>4</sup> of Sweden, in 1905-06, defined mild, non-paralytic types not before recognized, made the first systematic study of the disease from an epidemiological point of view, and found evidence that it was contagious, though usually slightly so. He directed especial attention to several factors in its spread, viz.: routes of travel, public gatherings of children, abortive or ambulant cases, and healthy intermediate carriers. In the spring of 1909 Landsteiner and Popper<sup>5</sup> succeeded in transmitting the disease to two monkeys by inoculating them with the spinal cord of a child who had died of infantile paralysis. Later in the year Flexner and Lewis<sup>6</sup> obtained the same results, and further transmitted the infection from monkey to monkey through an indefinite number of passages. To Harbitz and Scheel of Norway we are indebted for formulating the pathologic anatomy of the affection.

<sup>5</sup> Zeit. f. Immun., Orig., 1909, II, 377.

<sup>6</sup> Jour. A. M. A., 1909, LIII, 639.

The name, infantile paralysis, is misleading, for adults are attacked and paralysis is not constant. The period of incubation is not known, although stated to be 5 to 10 days, commonly 6. The case fatality rate varies in different epidemics from 4 to 27 per cent. Gastro-intestinal symptoms and fever lasting 3 or 4 days often precede the paralysis, although a child may go to bed well and wake up in the morning with paralysis and a slight fever.

Epidemics of poliomyelitis have prevailed in all quarters of the world. The disease has been most prevalent in the northern parts of Europe and of the United States. Epidemics have been more severe, and the case rates have been higher, in small towns and rural districts than in the more densely populated cities. Even in the cities the disease does not especially strike the crowded districts. Cold countries having marked seasonal variations in temperature have been most affected, but the disease is most prevalent in the warm, dry months, from May to November in the northern hemisphere and November to May in the southern hemisphere. A severe outbreak (3,840 cases and 380 deaths) occurred in Sweden in 1911 in the late fall—October and December. Sporadic cases may occur at any time throughout the year. The great majority (75 per cent.) of cases occur in children under five years of age and 98 per cent. under 15 years.

From the standpoint of prevention it is important to note that social and hygienic conditions apparently have no influence whatever in determining the infection. All classes are affected in about equal proportion. Sir Walter Scott gives a graphic account of his own case.<sup>7</sup>

Infantile paralysis has the ear marks of a new infection, although instances of sudden paralysis in babies said to be due to carelessness of the nurse, are found in the literature of antiquity and some of these are assumed to have been cases of infantile paralysis. It is quite certain that the disease has become more and more common and more wide-

<sup>7</sup>"I shewed every sign of health and strength until I was about eighteen months old. One night, I have often been told, I shewed great reluctance to be caught and put to bed; and after being chased about the room, was apprehended and consigned to my dormitory with some difficulty. It was the last time I was to show such personal agility. In the morning, I was discovered to be affected with the fever which often accompanies the cutting of large teeth. It held me three days. On the fourth, when they went to bathe me as usual, they discovered that I had lost the power of my right leg. My grandfather, an excellent anatomist as well as physician, the late worthy Alexander Wood, and many others of the most respectable of the faculty, were consulted. There appeared to be no dislocation or sprain; blisters and other topical remedies were applied in vain. When the efforts of regular physicians had been exhausted, without the slightest success, my anxious parents, during the course of many years, eagerly grasped at every prospect of cure which was held out by the promise of empirics, or of ancient ladies or gentlemen who conceived themselves entitled to recommend various remedies, some of which were of a nature sufficiently singular. But the advice of my grandfather, Dr. Rutherford, that I should be sent to reside in the country, to give the chance of natural exertion, excited by free air and liberty, was first resorted to." From "The Life of Sir Walter Scott," by J. G. Lockhart, p. 13.

spread of late years. The increase cannot be wholly accounted for by the fact that the disease is now better known and more readily recognized.

Following the first record of the disease in an epidemic form in Sweden in 1881, some groups of cases were reported in 1882 in Italy, and in 1886 in Norway, Germany and France. All these epidemics were small in numbers attacked. In 1887, Medin described an epidemic in Stockholm of forty-four cases, and this is the first important work on the subject. In 1894, an epidemic of 132 cases occurred in Rutland, Massachusetts, which was recorded by Caverley and McPhail. Small epidemics are recorded in the "nineties" in Italy, France, Australia, England, and America, and a larger one occurred in Vienna (forty-two cases), in 1898, and in Norway and Sweden in 1899. The last was described by Wickham. In the middle of the next decade, 1900 to 1910, the record of cases, which before had been limited to two figures, now reached to four figures, and during the years 1903-07, it may be said that the disease was pandemic in Norway and Sweden. During the years 1907-10, large epidemics occurred in the states of New York and Massachusetts. At the same time epidemics of the disease were recorded in Australia (Stephens), in Vienna (Zappert), Westphalia (Krause and Reckzek), in Paris (Netter), in Austria (Furnatt, Potpeschnigg, Lindner and Mallu), Switzerland (Hagenback), and in Russia (Jogichess).

Of the 8,054 cases reported in 5 years (1905-09), the United States contributed 5,514 cases or about five-sevenths of the total number. The number of outbreaks and the number of cases have progressively increased, as shown in the following table:

	Cases	Outbreaks	Av. No. of Cases per Outbreak
1880-1884 .....	23	2	11.5
1885-1889 .....	93	7	13.
1890-1894 .....	151	4	38.
1895-1899 .....	345	23	15.
1900-1904 .....	349	9	39.
1905-1909 .....	8,054	25	322.

Since 1910, the disease has shown a rapid increase. From 1910 to 1914 (inclusive), 18,800 cases were reported in the United States; and 31,500 cases in the two years 1915 and 1916. The disease was progressive, the epidemic grew in extent and intensity, until it became pandemic, and in 1916 swept the United States, involving numbers far in excess of anything hitherto recorded. In 1916 there were 29,000 cases and 6,000 deaths; Massachusetts reported 1,926 cases, and New York City alone over 8,928 cases and 2,407 deaths.<sup>8</sup> Since 1916 the disease

<sup>8</sup> See the splendid epidemiological study of the epidemic of 1916, *Public Health Bulletin No. 91*, July, 1918, by Lavinder, Freeman and Frost. Also the

has subsided, but has left thousands of crippled children. The after-care of infantile paralysis has become a public health problem of considerable magnitude, which requires special clinics under the care of competent orthopedists with muscle trainers and social service workers. (See Reports of the Harvard Infantile Paralysis Commission.)

The virus of the disease is present in greatest virulence or concentration in the spinal cord of infected persons and animals. One one-hundredth of a cubic centimeter of an emulsion of cord, or less, is sufficient to infect a monkey. The virus is also quite constantly present in the brain and other organs and tissues, as, for instance, the mucous membrane of the nose and pharynx, the mesenteric glands, the axillary and inguinal lymph nodes, also in the blood, and in the cerebrospinal fluid. The virus has been demonstrated in the intestinal secretions. The suspicion that the alvine discharges may, therefore, be virulent is sufficient indication that they should be disinfected in all cases until further knowledge of the subject is at hand. The virus has been grown by Flexner and Noguchi<sup>9</sup> as minute globoid bodies arranged in pairs, chains and masses in artificial cultures.

The experimental disease in monkeys may be produced by injecting the virus directly into the central nervous system, preferably the brain. Monkeys may also be infected by introducing the virus subcutaneously or into the peritoneal cavity, and even by intravenous inoculation. They have been infected by placing virulent material upon the healthy mucous membrane of the nose and also by inhalation of the infectious material forced into the trachea, and finally by introducing the virus into the stomach, along with an opiate, to restrain peristalsis. Leiner and Weisner have infected monkeys through the uninjured nasal mucous membrane. I have obtained similar results. Monkeys have so far never been known to contract the disease "spontaneously," even though they are kept in intimate association with infected monkeys. There are many paralytic diseases of the lower animals, but, so far as known, infantile paralysis as a natural infection is peculiar to man.

**Resistance of the Virus.**—The virus of infantile paralysis is killed by a temperature of 45° to 50° C. in half an hour; also by comparatively weak disinfectants, such as a 1-500 solution of permanganate of potash, 1 per cent. menthol in oil, a powder containing menthol, 0.5 per cent., salol, 5 per cent., boric acid, 20 per cent. (Landsteiner and Levaditi), and a dilution of perhydrol (Merck) equivalent to 1 per cent. of peroxid of hydrogen. The virus is not destroyed by very low temperatures nor by drying over caustic potash, or *in vacuo* for a considerable period. A virulent cord has been kept for almost 5 months in pure glycerin

"Epidemic of Poliomyelitis in New York City in 1916," published by the Department of Health, New York City.

<sup>9</sup> *Jour. A. M. A.*, Feb. 1, 1913, LX, 3, p. 362.

without losing its activity, resembling in this respect rabies, vaccinia, and other filterable viruses, and differing for the most part from non-spore-bearing pathogenic bacteria which are usually killed by pure glycerin in a short while. The virus remains virulent in ordinary water for 31 days,<sup>10</sup> and the same length of time in milk, first sterilized by heat.

**Immunity.**—One attack of infantile paralysis apparently confers a high degree of immunity. Recurrent cases and second attacks have been reported. Monkeys which have recovered from the infection show a high degree of resistance, in that they are not susceptible to infection by again inoculating them, and their blood serum contains antibodies capable of rendering the virus harmless. That is, if the blood serum of an immune monkey is mixed with an emulsion of virulent spinal cord and the mixture allowed to stand for several hours, the virus is no longer capable of producing the disease in susceptible animals. This property has been used by Anderson and Frost to corroborate the clinical diagnosis in abortive cases. The blood of a person who has not had the disease does not neutralize the virus; therefore, if the injection of the virus previously treated with human serum fails to produce the infection in susceptible monkeys, it may be taken as evidence that the serum contained specific antibodies and came from an individual who has had the disease. Monkeys often fail to respond to injection with fresh virus. Negative results must therefore be studied critically.

**Modes of Transmission.**—*Contact theory* (based upon the assumption that the virus is discharged from the mouth and nose and enters through the same channel).—There is evidence to support the theory that the disease is directly transmissible from person to person and there is a suspicion that healthy carriers play an important rôle in spreading the infection. This view was enunciated by Wickman and received support through the experiments of Kling, Pettersson and Wernstedt, and also Flexner. It is known that the mucous membrane of the nose and throat contains the virus, and in one case the salivary glands were shown to be infective. Osgood and Lucas demonstrated that the nasal mucous membrane of two monkeys experimentally inoculated with poliomyelitis remained infective for 6 weeks in one case and 5½ months in another. This observation strengthens the suspicion of the existence of chronic human carriers. If healthy carriers continue to spread the infection months after the attack, it increases the difficulty of suppressing the disease, and further renders doubtful the efficiency of strict isolation and prophylactic measures directed only to persons in the acute stage of the disease. The fact that the mucous membrane contains the virus is not, however, sufficient proof that the virus is liberated and discharged in sufficient amount in the secretions from the mouth and nose to be a menace. In a series of 18 cases Rosenau,

<sup>10</sup> Levaditi and Pasti, *Annal. de l'Inst. Pasteur*, XXV, 11, 805.

Sheppard and Amoss<sup>11</sup> were unable to demonstrate the virus in the nasal and buccal secretions obtained from persons in various stages of convalescence. Strauss<sup>12</sup> had similar negative results in a series of 10 cases. Amoss and Taylor<sup>13</sup> demonstrated that the normal nasopharyngeal secretions are able to neutralize the virus of infantile paralysis, and this may account for the negative results. Flexner and Amoss<sup>14</sup> find that the protective power of the nasal mucosa is not in itself adequate to prevent infection with the virus placed on it, since slight injury to such independent structures as the meningeal-choroid plexus favors the passage of the virus from the nose to the central nervous system. On the other hand, Kling, Pettersson and Wernstedt<sup>15</sup> report successful results: by experiments upon monkeys they demonstrated the infectiousness of buccal and intestinal secretions of living subjects.

The latest views of Flexner and Amoss<sup>16</sup> are that the virus is regularly present in the nasopharynx in cases of infantile paralysis in the first days of illness and especially in fatal cases; that it diminishes relatively quickly as the disease progresses, except in rare instances; and that it is *unusual* for the carrier state to develop. Hence, the period of greatest infectivity would be early in the disease.

*The Insect-borne Theory.*—Infantile paralysis shows no tendency to prevail in congested centers or to spread in hospitals, schools, institutions, and other crowded places; its seasonal prevalence corresponds to the seasonal prevalence of most insects, and does not correspond to the seasonal prevalence of diseases spread through secretions of the mouth and nose, such as diphtheria, scarlet fever, smallpox, etc. Many other factors, brought to light by the studies of the State Board of Health of Massachusetts upon the epidemiology of the disease, under the able direction of Dr. Mark Richardson, indicate that the disease is not a contagious one. These studies<sup>17</sup> gradually focused attention upon some insect, the stable fly (*Stomoxys calcitrans*) in particular. Rosenau and Brues<sup>18</sup> demonstrated that the virus may sometimes be transmitted from monkey to monkey through the bite of the stable fly. These results were

soon confirmed by Anderson and Frost.<sup>19</sup> The insect-borne theory seems to fit the case as the disease is known in Massachusetts. Subsequent work by Rosenau, Anderson and others has given negative results. Even though infantile paralysis may occasionally be transmitted experimentally by insects biting monkeys in a cage, it seems improbable that this is the way the infection is spread from man to man in nature.

*Other Theories.*—It has been suggested that the virus may be air-borne in the sense that it is carried in the dust. Neustaedter and Thro<sup>20</sup> claim to have infected monkeys from dust collected from sick rooms. Richardson believes the infection comes from rats. Infected food, or transmission through wounds and other means, have not been ruled out of consideration.

A favorite explanation of the epidemiology of the disease is to regard it as a very communicable disease like measles, and much more widespread in the community than indicated by the paralytic cases. Most cases are mild, escape notice and leave protection. In accordance with this theory only the occasional severe case with paralysis comes to clinical diagnosis. In accordance with this view, we are dealing with a very common infection, always present in the community, but which in recent years has gained an increased virulence.

**Prevention.**—No definite or effective system of prevention can be formulated until we are sure of the mode of transmission. Meanwhile health authorities are entirely justified in requiring cases to be reported, isolated, and all known lines of preventive measures applied, such as disinfection, screening, and guarding against insects, allaying unnecessary dust, etc. The infection must be fought as one conveyed from man to man directly. Until the modes of transmission of the disease are established, however, we can have no confidence in our prophylactic measures, which most resemble the old "shotgun" prescription.

The following measures are recommended: The patient should be isolated as completely as possible in a clean, bare room, well screened to keep out insects. This is a good practice despite the fact that the disease shows no tendency to spread in children's asylums, hospitals, and other institutions, or even in the home. The same statement, however, was made of typhoid fever not many years ago. Visiting should be interdicted and only the necessary attendant should be allowed to come in contact with the patient. All discharges, including sputum, nasal secretions, urine, and feces, should be thoroughly disinfected, and special care should be taken that cups, spoons, remnants of food, etc., which may have become contaminated by the patient are burned, scalded, or otherwise purified.

<sup>19</sup> Anderson, J. F., and Frost, W. H., *Pub. Health Reports*, Oct. 25, 1912, XXVII, 43, pp. 1733-1736.

<sup>20</sup> Neustaedter, M., and Thro., W. C., *N. Y. Med. Jour.*, Sept. 23, 1911, XCIV, 13.

Towels, bed linen, and other fabrics should be boiled or dipped into a germicidal solution strong enough to destroy the typhoid bacillus. The nurse and physician should observe the same precautions regarding their hands and clothing as are recommended in attending a case of scarlet fever.

The period during which the isolation should be maintained cannot even be guessed at. Children are usually not permitted to return to school for at least three weeks, but, if chronic carriers play the important rôle suspected, this time would be far too short in many instances.

Since the virus can be killed experimentally by a 1 per cent. solution of peroxid of hydrogen, antiseptic gargles, sprays, and nose washes of this solution have been used by the patients, the nurse, and physician, and other members of the family. Germicidal chemicals applied to the nasal mucosa on which the virus has been deposited have no protective action and are of doubtful value; in fact, such substances may affect unfavorably the protective properties of the nasal mucosa. They may even be objectionable by injuring the delicate mucous membrane and thus favoring infection.

Normal mucous membranes are protective against this as against other infections of the upper respiratory tract. According to Flexner and Amoss, the normal nasal mucosa is an invaluable defense against infection with the virus of poliomyelitis, and the number of healthy and chronic carriers of the virus is probably determined and kept down through the protective activities of this membrane.

In the presence of an epidemic, street and house dust should be kept down by sprinkling, oiling, and the other means employed for this purpose. Dust should be allayed whether there is an epidemic of infantile paralysis or not. During epidemics children should be kept away from public gatherings, prohibited from using public drinking cups, and special attention given to the diet to prevent gastro-intestinal disorders, for many a case of infantile paralysis starts with a digestive upset.

The prevention of deformities in paralyzed children is important. Massage, exercise and all active measures are contraindicated during the acute stage and as long as there is tenderness. Special attention must be given to maintain a normal position of paralyzed limbs so as to prevent deformities which develop quickly. As soon as acute symptoms have subsided, muscle training should be instituted.

**EPIDEMIC ENCEPHALITIS**

*Epidemic encephalitis*, also called encephalitis lethargica, infectious ophthalmoplegia, acute encephalitis, and nona, is an acute infection due to a specific virus which is assumed to enter the system through the nasopharynx, and like infantile paralysis has a special affinity for the central nervous system, although for different areas and elements. The disease is characterized by progressive lethargy or stupor, lesions in or about the nuclei of the third pair of cardinal nerves, and fever. Ophthalmoplegia occurs in 75 per cent. of the cases.

The only epidemic appearance of any similar disease in the past has been in connection with epidemics of influenza. Following the pandemic of 1889-90, the mysterious nona appeared in northern Italy, and then in Hungary, and spread to Germany, France and Italy. Camerarius described a grip epidemic in Tübingen in 1718 and mentioned a sleeping sickness (Schlafkrankheit) in connection with it. In 1768, Lepecq de la Cloture described a "coma somnolentum" after the grip, and Ozanann mentioned epidemics of "catarrhal fever" with "soporosite" as having occurred in Germany in 1745, in Lyons in 1800, and in Milan in 1802. The disease did not follow the influenza epidemic which swept this country in 1889-90, but was observed after the 1918-19 outbreak. Von Economo described cases occurring in Vienna during the winter of 1916-17, and since then, cases have occurred in England, the United States, and France.

Flexner<sup>21</sup> points out that lethargic encephalitis is a communicable disease, imperfectly understood. Amoss<sup>22</sup> states that lethargic encephalitis is an epidemic disease, the main manifestations of which relate to injury inflicted upon the central nervous system, in particular the basal ganglia of the brain. This distinguishes it from poliomyelitis, which affects in particular the gray matter of the spinal cord and medulla oblongata. Furthermore, infantile paralysis prevails especially in warm weather, whereas lethargic encephalitis is reported mainly in the winter season, although recently cases have arisen in the midsummer months. Infantile paralysis is readily transmitted to monkeys, whereas this is doubtful with lethargic encephalitis. The two diseases are further distinguished by the fact that the blood serum of convalescent cases of infantile paralysis neutralizes the virus of that disease, while the blood serum of convalescent cases of epidemic encephalitis lacks this power. Loewe and Strauss claim to have reproduced the disease in rabbits and monkeys by the inoculation of brain material and nasopharyngeal washings; also by means of cultures.<sup>20a</sup>

<sup>20a</sup> *Jour. Inf. Dis.*, Sept., 1920; confirmed in part by Levaditi and Havier.

<sup>21</sup> *Jour. A. M. A.*, Mar. 27, 1920, Vol. LXXIV, p. 865.

<sup>22</sup> *Jour. Exp. Med.*, Feb. 1, 1921, XXXIII, 2, p. 187.

**CHICKENPOX***(Varicella)*

Chickenpox (*varicella*) is usually regarded as one of the minor communicable diseases in that the mortality is low, complications and sequelae not frequent. Chickenpox is not always a harmless disease; when it runs through an institution with many small children it occasionally develops malignancy. It may leave disfiguring scars; sepsis or erysipelas sometimes originate in the pustules; complications, such as pneumonia, nephritis, and gangrene of the skin also occur.

Chickenpox is very readily communicable and spreads through families or institutions, and occurs in more or less widespread epidemics. The cause of the disease and its modes of transmission are not known. The virus is contained in the content of the vesicle. The vesicles appear early on the mucous membranes and rupture as soon as they appear, rendering the disease communicable early, even before the exanthem is in evidence. The mode of transmission is directly from person to person; indirectly through articles freshly soiled by discharges from an infected person.

The disease is peculiar to man; animal inoculations have so far proved negative. The period of incubation is probably from 14 to 16 days; the maximum for public health purposes is 21 days. One attack produces a definite immunity. No age is exempt.

Health officers should require cases of chickenpox to be reported, if for no other reason than that it is often mistaken for smallpox. The differential diagnosis between chickenpox and smallpox is often an important and difficult public health matter. The distinction may be made by introducing some of the contents of the vesicle into the skin of a well-vaccinated person. If smallpox, an "immediate" reaction results; if chickenpox, no reaction results. Monkeys are not susceptible to chickenpox, but may be given smallpox.

The differential diagnosis may be made in doubtful cases by a histological examination of the pock, or by inoculating the contents of the vesicle upon the cornea of rabbits. Vaccine bodies are found in sections of the skin lesion in smallpox, not in chickenpox; the vesicle of the former is multilocular, the latter unilocular. The vesicle upon the cornea of rabbits produced by smallpox is distinct and contains the vaccine bodies; the lesion resulting from chickenpox is trifling and does not contain the vaccine bodies.

Force and Beckwith<sup>23</sup> state that rabbits previously vaccinated with vaccine virus will give a marked intradermal reaction with smallpox

<sup>23</sup> *Jour. A. M. A.*, Vol. LXV, No. 7, August 14, 1915, p. 588, Force and Beckwith.

vesicle contents in from twenty-four to forty-eight hours, but will not give such a reaction with varicella vesicle contents. I have not been able to obtain clean-cut results with this test.

The prevention of chickenpox depends upon isolation and disinfection at the bedside. Children with chickenpox should not be permitted to go to school.

Kling<sup>24</sup> favors vaccination with chickenpox virus, in the face of an epidemic in an institution. The response to such vaccination is slight and local. The virus is taken from a fresh, clear vesicle and introduced into the skin. Eight days later red papules appear at the site of "vaccination," which next day develop into typical vesicles of chickenpox, with a slight reddened areola. There are no general symptoms. Previous vaccination with smallpox does not prevent a positive reaction to vaccination with chickenpox, thus emphasizing the essential difference between the two diseases. An epidemic of chickenpox at the Stockholm Children's Hospital in August, 1914, was cut short by vaccinating all the well children with the virus from a chicken pox. Steinert<sup>25</sup> also obtained successful results. Michael's<sup>26</sup> results are less convincing.

Hess and Unger<sup>27</sup> obtained an immunity to varicella by means of an intravenous injection of the contents of the vesicles. In 38 instances it failed to protect in only one case.

## GLANDERS

Glanders or farcy is a widespread communicable disease of horses, mules, asses, and other animals, and is readily communicated to man. Cats may become infected by eating the flesh of glandered horses. Goats also have the disease. Cattle are immune. Guinea-pigs and field mice are very susceptible by experimental methods; white mice have a natural immunity. In both man and horses it is remarkable for its fatality. The disease is characterized by the formation of inflammatory nodules either in the mucous membrane of the nose (glanders) or in the skin (farcy). The nodules break down, leaving crater-like ulcers. On the skin the farcy buttons break down and discharge an oily material. The mortality is about 50 per cent. Glanders occurs both as an acute and chronic disease.

Glanders is caused by the *Bacillus mallei*, which corresponds to the spore-free bacteria so far as its resistance is concerned. In general the bacillus of glanders is killed by the same agents used against the tubercle bacillus, which it resembles in some particulars.

The infection may be introduced into the system either through the

<sup>24</sup> *Berl. klin. Wochenschr.*, Nov. 10, 1913, L, 45, p. 2083.

<sup>25</sup> *Zeitschr. f. Kinderheilkunde*, July 28, 1920, p. 94.

<sup>26</sup> *Arch. of Pediatrics*, Sept., XXXIV, No. 9, p. 702.

<sup>27</sup> *Am. Journ. Diseases of Children*, July, 1918, XVI, p. 34.

skin or mucous membrane, and is usually communicated directly from the horse to man by contact with the infected discharges. The disease is sometimes communicated from man to man. Washerwomen have become infected from the clothes of a patient.

The bacillus of glanders does not have a spore. It is comparatively frail and readily destroyed by the usual physical and chemical germicidal agencies used against spore-free bacteria. The bacillus, however, is frequently protected by albuminous matter or buried in the dirt of stables, water troughs, harnesses, and other objects. While the naked germs of glanders are readily destroyed, they are frequently hard to get at; cleanliness is, therefore, imperative.

The prevention of glanders in man depends primarily upon the suppression of the disease in horses. The only difficulty in controlling the disease in horses lies in the early diagnosis and recognition of mild or missed cases, which are very common. Horses affected with occult or latent glanders are important factors in the propagation of the infection, especially in the crowded parts of cities. The clinical diagnosis in the frank cases usually is made without difficulty from the characteristic symptoms and the lesions, but laboratory aid is necessary to discover the mild and atypical cases.

**Diagnosis.**—The diagnosis of glanders may be made by: (1) the mallein test, both subcutaneous and ophthalmic; (2) the agglutination test; (3) the Strauss reaction; (4) isolation of *B. mallei* in pure culture; and (5) complement fixation. All these tests serve a definite purpose. However, the mallein test, the agglutination test, and the Strauss reaction have certain limitations. The isolation of the glanders bacillus in pure culture is definite and final, but time-consuming. There is no absolute relation between complement fixation, agglutination and mallein tests in horses. An apparently healthy horse should not be condemned because one of these tests is positive but the animal should be studied further.

*The Mallein Test.*—Mallein is a product of the glanders bacillus corresponding to tuberculin. The injection of mallein into normal animals produces no reaction, whereas the injection into glanderous animals causes a rise in temperature and a local reaction about the lesions. With the mallein test a large proportion of latent and occult cases of glanders can be diagnosed, but the test must be made and interpreted by an experienced veterinarian, else the results may be unreliable. The mallein test fails to give a typical reaction in a considerable number of glanderous animals; on the other hand, a reaction may follow the injection of mallein in the absence of active glanders. Thus mallein is not an entirely reliable diagnostic agent and has never been considered as specific in the detection of this disease as tuberculin for the diagnosis of tuberculosis.

The *ophthalmic test* for glanders is reliable, and has a great advantage over other tests on account of its very simple application. It is only necessary to drop into one of the eyes of the animal three drops of concentrated mallein, or to dip a camel's-hair brush into mallein and introduce this into the conjunctival sac. The reaction usually commences in five or six hours after the introduction of the mallein and lasts from twenty-four to thirty-six hours. A positive reaction is manifested by swelling of the eyelids and a purulent secretion from the tested eye. Irritation of the conjunctivae due to cold weather, dust and other irritating influences must not be confused with a positive reaction.

*The Agglutination Test.*—The agglutination test is of value in all cases of recent infection, the blood serum possessing a very high agglutinating power—1-1,000 and higher. In chronic glanders the agglutinating power of the blood may be very low—1-400 or less; in some cases even lower than that of normal blood serum—which may be 1-800 and even higher. It is, therefore, plain that agglutination tests alone do not constitute an entirely satisfactory diagnostic method for glanders. It may be used as an adjunct to other tests.

*The Strauss Reaction.*—The Strauss<sup>28</sup> reaction for the diagnosis of glanders consists in inoculating material containing virulent *B. mallei* into the peritoneal cavity of male guinea-pigs, which causes an enlargement of the testicles, involving the scrotum; the testes become glued to their sheaths. A positive reaction associated with organisms resembling those of glanders, and typical cultures obtained from the lesions, are unfailing evidence of the presence of the specific virus. Failure to obtain the reaction is not proof that a suspected specimen may not have come from a horse or animal with glanders. Arms<sup>29</sup> recommends that it is better to use more than one guinea-pig in testing suspected material, and that, before inoculating, it is well to make a microscopic examination as a guide to the dosage. A culture made from the swab often aids in the early diagnosis. Guinea-pigs should be kept under observation for a month, and if a lesion of any kind is present an autopsy should be made and cultures taken.

*The Isolation of B. Mallei in Pure Culture.*—The bacillus of glanders may be isolated by introducing some of the suspected material subcutaneously and also intraperitoneally into male guinea-pigs. In this way pure cultures may be obtained from the pus or necrotic foci in the spleen, which follow subcutaneous inoculation; or from the characteristic enlargement of the testicle which is observed in animals inoculated intraperitoneally. The organism isolated must be studied for cultural, morphological, and biological characters. The isolation of the bacillus in pure culture gives positive information of unquestioned

<sup>28</sup> *Compt. Rend. Acad. d. Sc.*, 1889, CVIII, p. 530.

<sup>29</sup> *Jour. A. M. A.*, LV, 7, Aug. 13, 1910, p. 591.

character in any critical case. The method is not generally applicable to the diagnosis of glanders because it requires too much time and may occasionally fail to discover the bacillus. One of the chief difficulties is that the material is usually grossly contaminated with other pathogens.

*Complement Fixation.*—In 1909 Schütz and Schubert<sup>30</sup> published the results of their important work on the application of the method of complement fixation for the diagnosis of glanders. The splendid results obtained constitute, without doubt, the most reliable method for the diagnosis of glanders which we have at our command at the present time. The complement fixation test is, in fact, one of the most specific of the biological tests in immunity. It is readily applicable to the case of glanders. It has, however, less value in testing the blood of mules than horses because of the larger percentage of false positives in the former. The essential elements used in the test are as follows:

The *hemolytic* mixture consists of the washed red blood corpuscles of a sheep and the blood serum of a rabbit which has been injected with the washed red blood corpuscles of a sheep. For preparation see page 583.

*Complement.*—The complement is contained in the fresh blood serum of a healthy guinea-pig. For preparation see page 581.

*Antigen.*—This is an extract obtained by shaking glanders bacilli in salt solution. The bacillus is grown in pure culture on 2 per cent. acid, 6 per cent. glycerin agar. A luxuriant growth upon the surface of the medium is usually obtained in 48 hours. This is suspended in 0.5 per cent. carbolized normal salt solution, heated to 60° C. for four hours in order to kill the bacilli. After heating, the dead bacilli are shaken in the salt solution in a special apparatus for eight to twelve hours. The bacilli are separated in the centrifuge and the clear supernatant liquid is drawn off and preserved with 0.5 per cent. phenol. The strength and specific quality of each extract must be determined by suitable methods of titration, by control tests.

*Technic.*—The test is carried out by adding together, in proper proportions, the following: (1) The blood serum of the horse to be tested; (2) the antigen (extract of glanders bacilli); (3) complement (fresh guinea-pig serum); and (4) the hemolytic system. If the blood serum of the horse to be tested contains the specific amboceptors, these will unite with the bacteria, fix the complement, and thus prevent hemolysis. If the blood serum of the horse to be tested does not contain these specific amboceptors, this fixation of the complement cannot take place and hemolysis results. Therefore, the absence of hemolysis

<sup>30</sup>Schütz and Schubert: "Die Ermittelung der Rotzkrankheit mit Hilfe der Komplementablenkungsmethode." *Archiv für wissenschaftliche und praktische Tierheilkunde*. Bd. 35, Heft 1 and 2, pp. 44-83, 1909.

means the presence of glanders, and vice versa. The tests must always be carried out with controls and carefully conducted as to the amount of each substance used, the temperature and time.<sup>31</sup> The technic and interpretation is precisely that of the Wassermann reaction (page 583), except that the antigen is an extract of the glanders bacilli.

**Prevention.**—When glanders is discovered or suspected among horses in a stable, the horses in the infected stable should be tested in the

FIG. 51.—DIAGRAMMATIC REPRESENTATION OF COMPLEMENT FIXATION. Mohler and Eichhorn, Bull. 136, B.A.I., U. S. Dept of Agriculture.

A, Hemolytic system.

B, Bacteriolytic system.

C, Negative reaction with normal horse serum.

D, Positive reaction with glandered horse serum.

manner above described. All animals with glanders should be destroyed without further consideration. After these animals have been killed and properly disposed of, the stable should be thoroughly cleansed and disinfected. All other horses which have in any way been associated with the infected animals should be carefully watched and tested again after three weeks, and, should there be no indication of the disease in the second test, the stable may be considered free from the infection; otherwise the infected animals should be destroyed and the tests repeated every three weeks until the disease has been eliminated.

<sup>31</sup> A complete description of the diagnosis of glanders by complement fixation, giving in full all the details, will be found in *Bull. 136*, Bureau of Animal Industry, Apr. 7, 1911, by Mohler and Eichhorn.

The eradication of glanders from a stable often means considerable loss and sometimes a sacrifice of valuable animals, but it is only through vigorous measures that the disease may be controlled. In the disinfection and cleansing, special attention should be paid to the stalls, harnesses, water troughs, bits, food containers, curry combs, sponges, and other objects exposed to the infection, which is eliminated mostly in the secretions from the mouth and nose. The common drinking trough for horses spreads the infection. The bacillus of glanders is very susceptible to bleaching powder, and it therefore is a cheap and reliable germicide for this purpose.

The personal prophylaxis of glanders in man depends upon the education and care of those who have to handle horses. In working with horses known to be infected rubber gloves, disinfection, and other methods of protection should be employed. Special care should be taken to prevent the spread of the disease through the discharges or by infected fomites from human cases. Fatal accidents have occurred in laboratories in research workers handling pure cultures of *B. mallei*.

## ANTHRAX

(*Splenic Fever. Charbon.*)

Anthrax has figured prominently in the history of bacteriology and immunology. The anthrax bacillus was the first pathogenic microorganism to be seen under the microscope, by Pollender in 1849. Anthrax was the first communicable infection to be experimentally transferred, when Davaine and Rayer,<sup>32</sup> in 1850, communicated splenic fever by the direct inoculation of blood containing "infusoria" to susceptible animals. Anthrax was the first bacterium to be grown in pure culture by Koch, in 1875.<sup>33</sup> Anthrax was the first dramatic demonstration by Pasteur,<sup>34</sup> in 1881, of the prophylactic value of an attenuated virus. Pasteur's work on anthrax closely followed similar experiments upon fowl cholera.

Anthrax belongs to that group of diseases which occurs primarily in the lower animals and secondarily in man. The infection is found especially in cattle, but also in horses, sheep, and other cloven-hoofed animals, and may be transmitted experimentally to mice, guinea-pigs, rats, and rabbits. Cold-blooded animals and birds, as well as dogs and swine, are refractory. Anthrax has a world-wide distribution; Russia is one of the principal foci of infection.

In man the infection may enter the skin (*malignant pustule*) or the lungs (*wool sorters' disease*), or may enter the digestive tract and

<sup>32</sup> *Mem. de la Soc. de Biol.*, 1850, p. 141.

<sup>33</sup> *Cohn's beit. zur biol. de pflanzen*, 1876, II, p. 277.

<sup>34</sup> *Compt. rend. de l'Acad. de Sc.*, XCII, 1881, p. 427.

produce intestinal lesions. Human anthrax is mostly an industrial disease contracted through the handling of skins, hair or animals. In anthrax of the skin the infection usually enters through slight abrasions, scratches, or small wounds, especially on the forearm, hand, neck, or face. In butchers or persons who handle infected carcasses or hides, it is apt to occur on the neck and shoulders.

Many cases of anthrax in the United States and in England have been traced to shaving brushes made of horse hair. In Massachusetts, 47 cases from shaving brushes were reported in 1917.

The spores have been carried to the skin by flies; Schuberg and Kuhn<sup>35</sup> have shown that anthrax may be transferred from animal to animal through the bite of the stable fly (*Stomoxys calcitrans*). Mitzmain obtained positive results with the stable fly and also with *Tabanus striatus*.<sup>36</sup>

**Wool Sorters' Disease**, or anthrax of the lungs, appears to be due to the inhalation of anthrax spores. It is observed only among persons who handle skins or who work with horse hair, wool, or other raw materials from animals afflicted with anthrax. The symptoms are like those of pneumonia; this form is frequently fatal.

The mode of transmission in intestinal anthrax is through meat from an anthrax cadaver. The usual heat of cooking or even canning does not necessarily kill anthrax spores. Intestinal anthrax is rare, but when it does occur is rapidly fatal.

**Resistance.**—The anthrax spore is exceedingly resistant to heat and external influences, such as dryness and sunlight, and also to germicidal agents. Its resistance may be compared to the tetanus spore, page 100.

**Prevention.**—A number of species of animals have a natural immunity to anthrax, and an artificially acquired immunity may be induced in cattle or sheep through the injection of attenuated cultures, in accordance with the classical method of Pasteur. These procedures are not applicable to man. The prevention of the disease in man must first be directed to a suppression of the infection in animals. The sick animals should be isolated, or, better, killed, and the carcasses burned or buried with lime at least three feet deep. The carcasses may be "tanked," that is, subjected to a prolonged exposure to steam under pressure. Tanks for this purpose are found in all the larger slaughter houses. It is important in handling the body of an animal dead of anthrax not to open it or shed blood, for the bacillus does not produce its spore except in the presence of oxygen, that is, the bacilli are mainly in the blood and internal organs and will not sporulate as long as access to the air is prevented.

<sup>35</sup> Arbeiten a. d. kaiserl. Ges.-Amt., Bd. XL, Heft 2, 1912,

<sup>36</sup> Public Health Reports, Jan. 9, 1914, p. 75,

The neglect of precautions in disposing of anthrax carcasses favors the spread of the infection through the activity of carrion feeders. Morris<sup>37</sup> has shown that buzzards may carry infection for long distances and contaminate clean ground or water through contamination on their feet and beaks. Dogs discharge anthrax spores in their feces 114 hours after feeding upon an anthrax carcass.

Gegenbauer<sup>38</sup> points out that animals may harbor anthrax organisms in their hair without themselves being infected.

The proper prevention of anthrax consists in the veterinary control of the disease among animals. The chief preventive measure so far as man is concerned is the disinfection of all raw material in those trades in which horse hair, hides, wool, and other substances liable to harbor the anthrax spore are handled. Veterinary surgeons who conduct autopsies upon anthrax animals should exercise special precautions, and, if practicable, wear rubber gloves.

Workers in leather tanneries, hair and wool factories can be protected by rubber gloves and rubber aprons. Protection is also afforded by an effective quarantine against all hides, wool, and hair from infected and suspected areas, and areas about which information is lacking. See also page 1322.

Proper ventilation should be provided to carry off the dust where hair and wool are handled, especially about carding machines. The refuse from tanneries and woolen mills should be properly disposed of; otherwise they may infect streams or fields through fertilizers.

A serum made by injecting horses with virulent anthrax bacilli is used as a therapeutic agent. Normal bovine serum also has curative value; neither of these sera is practical as a prophylactic.

**Disinfection.**—Steam disinfection is practicable for hair, but not for wool or hides. The wool fiber and hides are seriously damaged by the action of the steam. Wool may be disinfected by formaldehyd used as given below. The method preferred for hides is the hydrochloric acid-salt bath of Schattenfroh. Manufacturers object to the disinfection of hides with bichlorid of mercury and formic acid, according to the Seymour-Jones method, on account of the apparent injury of such treatment.

All hides, wool and hair from anthrax-infected and suspected areas, or areas about which information is lacking, should be disinfected. This disinfection should be done in the country where the hides, wool and hair are collected, preferably at the market center, where the work could be done under skilled supervision.

*Hair for Shaving Brushes.*—The disinfection of the hair used for shaving and lather brushes, in accordance with the requirements of

<sup>37</sup> *Louisiana Bull.* No. 136, Agr. Exp. Sta., Nov., 1912.

<sup>38</sup> *Arch. f. Hyg.*, 89, 202, 1920.

the United States Government,<sup>39</sup> is accomplished by one of the following methods: (a) by boiling the hair or bristles for not less than three hours; (b) by exposing the hair or bristles to steam under not less than fifteen pounds gauge pressure for not less than thirty minutes with a preliminary vacuum of not less than ten inches before turning on the steam; (c) by exposure to streaming steam for not less than six hours.

*Shaving Brushes.*—Any brushes found in the market which do not bear the name or the trade mark of the manufacturer should be regarded with suspicion, and should be returned to the source from which they were secured, or should be disinfected.

For the sterilization of the brushes themselves the following procedure is believed to be effective:

The brush should be soaked for four hours in a 10 per cent. solution of formalin (by formalin is meant a 40 per cent. solution of formaldehyd). The solution should be kept at a temperature of 110° F. and the brush so agitated as to bring the solution into contact with all hair or bristles.<sup>40</sup>

Obviously it would be better to avoid the use of horse hair in shaving brushes, because of the extraordinary hazard from them.

*Wool.*—The Departmental Committee on Anthrax<sup>41</sup> recommends the following for the disinfection of wool, goat hair and camel hair: A preliminary agitation with an alkaline solution of soap in water at a temperature of 102° to 110° F.; exposure for 20 minutes in a 2 to 2½ per cent. solution of formaldehyd in water at a temperature of 102° to 105° F. The hair is then dried in a current of air at 160° F., and allowed to stand a short time in order that the formaldehyd may complete its germicidal action.

*Hides and Skins.*—(1) The Seymour-Jones method: To 1 pound of perchlorid of mercury add 500 gallons of water, and to this mixture add 5 gallons of formic acid (commercial 50 per cent. strength). In this bath steep the material for twenty-four hours.

(2) The Schattenfroh method: In a 2 per cent. hydrochloric acid solution to which 10 per cent. of common salt has been added steep the material for 40 hours at a temperature of 60°-70° C. A quicker method can be used by substituting a 1 per cent. solution of hydrochloric acid and 8 per cent. of salt, provided the temperature of the solution is maintained at 40° C. (104° F.) for a period of six hours.<sup>42</sup>

<sup>39</sup> Interstate Quarantine Regulations, Treasury Dept., Washington, July 30, 1918.

<sup>40</sup> Report of the Departmental Committee on Anthrax, Vol. II, London, 1918.

<sup>41</sup> Public Health Bureau Circular Letter No. 136, dated July 31, 1918.

<sup>42</sup> Industrial Bull. No. 6, Commonwealth of Mass., State Bd. of Labor and Industries, p. 7.

*Hair, Bristles and Pigs' Wool.*—(1) By letting a current of steam act on the material for not less than one-half hour at a pressure of 17 pounds (0.15 above atmospheric pressure);

(2) By boiling for at least one-quarter of an hour in a solution containing 2 per cent. of permanganate of potassium, and subsequent bleaching with a 3 or 4 per cent. solution of sulphurous acid;

(3) By boiling in water for not less than two hours.

## FOOT-AND-MOUTH DISEASE

Foot-and-mouth disease is also known as aphthous fever, epizootic catarrh, and eczema contagiosa. It is an acute and highly communicable disease, generally confined to cloven-footed animals, and characterized by an eruption of vesicles on the mucous membrane of the mouth and on the skin between the toes and above the hoofs; seldom on the udder or other parts of the body. The vesicles rupture, leaving superficial erosions which sometimes develop into ulcers. Other symptoms are: salivation, tenderness of the affected parts, loss of appetite, lameness, emaciation, and diminution in the quantity of milk secreted.

Foot-and-mouth disease is primarily a disease of cattle and secondarily of man. It also affects hogs, sheep, goats, buffalo, American bison, camel, chamois, llama, giraffe, antelope, and even dogs and cats are said to occasionally become infected. Horses and fowl are not susceptible.

The disease prevails in European countries, especially Russia, also South America, Asia and Africa, and occasions great economic loss. The mortality is low; the serious losses depend chiefly upon the diminution of the milk secretion and the loss of flesh in the affected animals as well as the disturbances of quarantine. It occurs as widespread epizootics, especially in the warm season.

Foot-and-mouth disease has appeared in the United States only on six different occasions—in 1870, 1880, 1884, 1902-3, 1908, and 1914. Every outbreak on American soil has thus far been followed by its complete suppression through the application of well-known preventive measures, such as isolation, destruction and burial of the affected herds, disinfection, restriction of the movements of cattle, and a systematic inspection of all farms in the infected area to detect cases of the disease.

Animals may be infected directly, as by licking, and in calves by sucking, or indirectly by fomites such as infected manure, hay, utensils, drinking troughs, railway cars, animal markets, barnyards, and pastures. The spread of the disease is due largely to carrying of the infection on the hands of persons who examine, milk, or otherwise come in contact with diseased animals.

Veterinary inspectors must take unusual precautions not to spread the infection in their efforts to control it.

Löffler and Frosch<sup>43</sup> in 1898 showed that the virus will pass the finest porcelain filters. This was the first "ultramicroscopic" virus discovered. The specific principle is contained in the serum of the vesicles; in the saliva, tears, milk, and various other secretions and excretions; also in the blood until the eruption comes out, then it disappears.

No definite immunity is rendered by an attack. The period of incubation is variable, usually from two to six days or longer, exceptional instances being prolonged to fifteen or even eighteen days.

The disease in man is a direct counterpart of that in cattle. The infection is transmitted to man through the ingestion of raw milk, buttermilk, butter, cheese, and whey from animals suffering with foot-and-mouth disease. It may also, though more rarely, be transmitted directly from the salivary secretions or other infected material which gains entrance through the mucous membrane of the mouth. It is doubtful whether the disease can be transmitted to man by cutaneous or subcutaneous inoculations, though it is probable that the infection may be communicated if the virus enters the blood directly through wounds of any kind. Children are most frequently infected by drinking unboiled milk during the time in which the disease is prevalent in the neighborhood; while persons in charge of diseased animals may become infected through contact with the affected parts or by milking, slaughtering, or caring for the animals. The disease is usually mild in man; death practically never results, except in weakened children, and then from secondary complications.

The original experiments of Löffler and Frosch, as well as recent experiments which have been made in Denmark and Germany, indicate that the virus is destroyed comparatively readily by heat or the usual germicides, except phenols and cresols, which are unreliable for this and other filterable viruses. Milk pasteurized at a temperature of 60° C. for 20 minutes is safe.

Foot-and-mouth disease has a special interest on account of the fact that it may be associated with vaccinia. Vaccine virus has been known to contain the infection of foot-and-mouth disease.<sup>44</sup> Glycerin acts as a preservative for the virus of foot-and-mouth disease, so that it may remain viable in glycerinated vaccine virus a very long time. No instance of the transmission of foot-and-mouth disease to man through vaccine virus has been recorded, and it is doubtful, in view of the known facts, whether it is possible to reproduce the disease in man by the cutaneous inoculation commonly used in the process of vaccination.

<sup>43</sup> *Deut. med. Wochenschrift*, 1898, Vol. XXIV, p. 80.

<sup>44</sup> "The Origin of the Recent Outbreak of Foot-and-Mouth Disease in the United States," by Mohler and Rosenau, *Cir. 147*, Bureau of Animal Industry, Dept. of Agriculture, 1909.

The prevention of foot-and-mouth infection in vaccine virus is assured through federal inspection and through special tests. See Vaccine Virus, page 24.

The prevention of foot-and-mouth disease consists (1) in a cattle quarantine, to keep it out of countries where it does not exist; (2) in the elimination of the disease in cattle through isolation of infected herds, destruction and burial of the sick animals, and disinfection; (3) the disease in man may be avoided by care in the selection of the animals from which milk is taken or by pasteurization of the milk when foot-and-mouth disease is prevalent.

Lisboa and da Rocha<sup>45</sup> report good results from the use of a vaccine which confers an immunity lasting from four months to a year.

### MALTA FEVER

Malta fever is a general infection not unlike other specific bacteriemias, such as typhoid fever. It is caused by the *Micrococcus melitensis*, discovered by Bruce in 1887 during the earlier days of bacteriology. Clinically the disease is characterized by profuse perspiration, constipation, frequent relapses often accompanied by pains of a rheumatic or neuralgic character, and sometimes swelling of the joints or orchitis. Malta fever is further characterized by its low mortality and long-drawn-out and indefinite duration. It prevails especially about the Mediterranean basin. Malta fever is a disease primarily of goats, secondarily of man.

Gentry and Ferenbaugh<sup>46</sup> in 1911 found a nest of malta fever throughout the older goat-raising sections of Texas. This endemic center embraces an area approximately 300 miles along the Rio Grande extending 90 miles to the north. All the cases of malta fever found have occurred in territory devoted to goat raising, and all the patients there gave a history of drinking unboiled goats' milk, or were associated with the goat-raising industry. The *Micrococcus melitensis* was isolated from several of the cases.

**Modes of Transmission.**—From experimental evidence it would appear that the infection of malta fever may be taken in through wounds, the mucous membranes, or by food and drink. The usual mode of infection is by drinking raw goats' milk. The *Micrococcus melitensis* leaves the body in various secretions and excretions. Great numbers of the cocci in pure cultures may appear in the urine. The milk of goats also contains the virus. All the secretions from the body must be regarded as infectious until further knowledge on the subject is at

<sup>45</sup> Mem. de Inst. Oswaldo Cruz, 1920, XII, No. 1, p. 66.

<sup>46</sup> Jour. A. M. A., Aug. 26, Sept. 9, Sept. 23, Sept. 30, 1911.

hand. In man the coccus may be isolated from the spleen, lymph glands, bone marrow, and mammary glands. In goats it first disappears from the blood, then the spleen, and, last of all, from the mammary glands.

Goats are susceptible to malta fever and continue to discharge the infection in the milk for a long time. The disease is usually contracted by drinking such infected milk. While this is the common mode of infection, occasional cases doubtless arise through other sources; thus one case which arose in England is supposed to have been conveyed from son to father by using a clinical thermometer in the mouth immediately after its use by the patient. Monkeys may readily be infected either by the inoculation of pure cultures or by feeding them. At least five accidental infections have occurred in bacteriological laboratories, one in Washington. Macfadyen lost his life from a laboratory infection with the *Micrococcus melitensis*. This microorganism has, therefore, more than complied with all the requirements of Köch's laws.

There has long been a suspicion that malta fever may be conveyed through the bite of an ectoparasite. In fact, Captain Kennedy was able experimentally to infect a monkey as a result of bites of mosquitoes (*Culex pipiens*) which had fed on patients suffering with malta fever. This probably was an instance of mechanical transference of the infection, corresponding in all respects to a laboratory inoculation with fresh virulent material from a hypodermic syringe. This cannot be a frequent way by which the infection is transmitted in nature, for the specific organisms are found in small numbers in the peripheral blood of malta fever patients. The British Commission found the *Micrococcus melitensis* only four times from a total of 896 mosquitoes studied.

From the fact that the micrococcus may be successfully introduced either by ingestion, or by inoculation, or through the mucous membranes, it is evident that occasionally cases may receive their infection through a great variety of means, such as insect bites and other wounds, infected food, and the various modes of contact infection. Contact infection, however, probably plays a minor rôle, for there is evidence that the disease is not, as a rule, directly transmitted from the sick to the well.

There is also experimental evidence to show that monkeys can be infected by dry dust artificially contaminated with cultures of the *Micrococcus melitensis*. The path of entrance may be through the nares, throat, respiratory passages, or alimentary canal. Dry dust contaminated with the urine of cases of malta fever has given rise to infection in goats but not in monkeys. The experience gained during the work performed in Malta during 1904 and 1905 has convinced Horrocks that men are more susceptible than monkeys and goats. Shaw's work on ambulatory cases of malta fever among Maltese has also shown that opportunities for the creation of infected dust were plentiful in Malta.

Infected dry dust as a mode of transmission cannot, therefore, be discarded.

**Goats' Milk and Malta Fever.**—We are indebted to the six reports of the British Commission for the investigation of Mediterranean fever (1905-1907) for the fact that malta fever is chiefly spread through goats' milk. Before the researches of this commission the common mode of infection was not definitely known.

The usual source of milk in Malta is the goat. The udders, which are abnormally long, often touch the ground and are very liable to be soiled. It was first shown by Zammit in the report of 1905 that goats could be infected by feeding them with the *Micrococcus melitensis*. In the same year Major Horrocks discovered the *Micrococcus melitensis* in the milk of an apparently healthy goat. Further studies showed that one or more healthy goats in every herd were excreting the *Micrococcus melitensis* in their milk and urine, and that about 50 per cent. of the goats reacted positively when examined by serum agglutination tests. All the available evidence points to their food as the main vehicle of infection in goats. The young goats, of course, are infected through their mother's milk. Horrocks and Kennedy consider that 10 per cent. of the goats supplying milk to various parts of Malta excrete the *Micrococcus melitensis* in their milk. The excretion of the specific micro-organisms may continue steadily for three months without any change occurring in the physical character or chemical composition of the milk and without the animal exhibiting any signs of ill health. On the other hand, the excretion of the *Micrococcus melitensis* in the milk may be intermittent, appearing for a few days and then disappearing for a week or more.

Major Horrocks in *Report No. 5* of the British Commission shows a direct relation between the number of goats in Gibraltar and the number of cases of malta fever. With the reduction in the number of goats in Gibraltar there was also a decrease in the number of cases, so that finally, when the number of goats had decreased to about 200, in 1905, malta fever had practically disappeared.

The story of the steamship *Joshua Nicholson* is instructive in showing the relation between goats' milk and malta fever in man. Sixty-one milch goats, all healthy in appearance and good milkers (many being prize animals), and four billygoats were shipped on board the cargo steamer *Joshua Nicholson* August 19, 1905, at Malta for passage to the United States via Antwerp. Many of the ship's company partook freely of the milk. The officers drank "mixed" milk collected in a large vessel; the members of the crew each obtained the "whole" milk from one goat in his own separate pannikin. Subsequent bacteriological examination resulted in the recovery of the *Micrococcus melitensis* from the milk of several of the goats. Of 23 men on board the steamer who drank

the goats' milk on one or more occasions, no evidence whatever is available as to 13, while of the remaining 10, 9 suffered from febrile attacks, 5 of them yielding conclusive evidence of infection with the *Micrococcus melitensis*.

*The Micrococcus Melitensis*.—The *Micrococcus melitensis* is readily destroyed by heat. I have shown that 60° C. for 20 minutes is sufficient to destroy this organism in milk and provides at the same time a liberal margin of safety. It is not destroyed at 55° for a short time, but succumbs in one hour; the majority die at 58°; at 60° all are killed. Phenol, 1 per cent., destroys the coccus in 15 minutes. While this micrococcus shows a comparatively feeble resistance against heat and the ordinary germicides, it shows a remarkable resistance to dryness, for it may remain alive in this state for months.

The micrococcus grows well, but slowly, upon artificial culture media. Visible colonies do not appear until about the fifth day. It may be kept alive indefinitely by transplanting to subcultures at frequent intervals. Exceedingly high agglutinating power develops in persons suffering with malta fever—sometimes as high as 1-100,000. In such cases the proagglutinoid zone may appear, that is, the serum may refuse to agglutinate in low dilutions, such as 1-100, but agglutinate actively in higher dilutions, such as 1-1,000.

Meyer and Shaw<sup>47</sup> call attention to the fact that it is not possible to distinguish between *Micrococcus melitensis* and *Bacillus abortus*. Feusier and Meyer<sup>48</sup> show a similarity in agglutinins.

**Prevention.**—Our knowledge of the cause and modes of transmission of malta fever makes the prevention of this disease a comparatively simple problem. The infection must first be eliminated in the goats. Until this is done goats' milk should be pasteurized. Patients having the disease should be treated upon the same principles laid down for typhoid fever, in order to prevent the spread of the infection through food, fomites, and contact. Convalescents should not be released until the micrococcus has disappeared from the urine. General sanitary measures, such as the suppression of flies and mosquitoes, allaying dust, and the promotion of general cleanliness, should not be neglected.

## YAWS

(*Framboesia tropica*)

Yaws is a communicable infection caused by the *Treponema pertenue*, described by Castellani in 1905. It is not a "venereal" disease, but closely resembles syphilis. It is named from the raspberry-like (fram-besiform) appearance of the eruption.

<sup>47</sup> *Jour. Inf. Dis.*, Sept., 1920, Vol. XXVII, No. 3, p. 173.

<sup>48</sup> *Ibid.*, p. 185.

Yaws is essentially a tropical disease and exists in Africa, especially on the west coast; in Asia, it is common in the Malay Peninsula, Assam, Upper Burma, Siam, Java, Batavia and Ceylon. In America, it is common in the West Indies, in British Guiana, Venezuela, Colombia and Brazil. Cases have been reported from the southern United States. Yaws also occurs in northern Australia and in many of the Pacific islands.<sup>49</sup>

*Treponema pertenue* of yaws closely resembles *Treponema pallidum* of syphilis. They are distinguished only by animal tests; thus, monkeys immunized with *pertenue* do not become immune for *pallidum*. The parasite is found constantly in the primary lesion and in the unbroken papules of the general eruption. It may also be found in the spleen, lymph glands and bone marrow.

Paulet in 1848 inoculated 14 negroes with the secretions from fram-betic granulomata. All of them developed yaws in from 12 to 20 days. Syphilitic patients may contract yaws naturally and experimentally; yaws patients may likewise contract syphilis. The two diseases are therefore distinct.

Yaws is usually conveyed by direct contact. It appears, however, that there must be some abraded surface or small wound, for the parasite probably cannot enter through the normal skin. Women are frequently infected by their children, the primary lesion appearing on the mammae. Castellani believes that the virus may also be transmitted by insects, especially flies.

Salvarsan and neo-salvarsan are efficacious. Mercury is useless. Prevention consists therefore in the treatment of all active cases so as to destroy the foci of infection. Personal prophylaxis in endemic centers consists in avoiding native contact and promptly treating the slightest abrasion of the skin with an active germicide. Patients should be isolated until cured. The skin lesions should be dressed and other measures used to guard against infection through the agency of flies and other insects. Traveling clinics in endemic centers for the administration of salvarsan, organized after the manner of the hookworm work, could control yaws. Work of this kind has been demonstrated in Santo Domingo.

## LEPROSY

Leprosy is a contagious disease in the sense that it is probably always communicated directly from the sick to the well, but prolonged and intimate association with a leper ordinarily seems necessary to contract

<sup>49</sup>It has been suggested by Hume, Adams and others that yaws was the disease which afflicted the Israelites during their emigration from Egypt, and that therefore the term "saraat" in the thirteenth chapter of Leviticus does not mean leprosy as usually translated.

the infection. The degree of the contagiousness varies very much, depending upon conditions not well understood, but it is plain that leprosy shows little tendency to spread in any of the more highly civilized nations practicing personal cleanliness and enjoying the benefits of modern sanitation.

In many localities the introduction of even a number of lepers does not lead to the spread of the infection.

When the standards of living improve, the disease tends to diminish. The fear of the disease is almost without parallel. Leprosy prevailed in epidemic form in Europe in the middle ages, but the disease has disappeared from central Europe, remaining only upon the fringe of the Continent, in Norway, Sweden, Spain, Italy, Greece, Turkey, Russia, and Finland. There are a considerable number of cases of local origin in Austria (Bosnia and Herzegovina), and a few in Germany (Memel), France, and Bulgaria. It is estimated that there are from 5,000 to 6,000 lepers in the Philippine Islands, and there are many cases in China and Japan. In India the census of 1910 shows an increase from 100,000 to 110,000 during the previous ten years. Leprosy is also on the increase in southern Africa (Bayon); in Basutoland alone it is estimated (1912) that there are 3,000 lepers, in a population of about 270,000. The greatest incidence is found among the natives of the Hawaiian Islands, where one in every 40 or 50 have the disease. Leprosy began to attract attention in the Hawaiian Islands about 1859, and there found conditions particularly favorable for spread. Precisely when it was introduced is uncertain.

In 40 years close to 5,000 cases were reported. A Government Commission in 1902<sup>50</sup> took a census of the lepers in the United States and found 278. Of these 145 were born in the United States and 186 probably contracted the disease in the United States. Of the entire number 72 of the cases were isolated and 205 were at large. Brinckerhoff again studied the prevalence of leprosy in the United States in 1909 and found 139 cases. The official figures for 1912 are 146.<sup>51</sup> Competent leprologists believe that the total number of cases is not far from 500.

It is evident that the disease is not markedly on the increase in our country and that, while it may be contracted here, it is "contagious" with great difficulty. There are three foci of leprosy in the United States: one among the Scandinavians in the region of the Great Lakes,

<sup>50</sup> White, Vaughan, and Rosenau, *Document No. 269*, 57th Congress, 1st Session, 1902.

<sup>51</sup> Complete returns from only 18 states. The incompleteness of the official returns is indicated by the fact that New York State acknowledged only 5 cases, whereas at a recent medical meeting more than that number of cases were shown in New York City alone. The laws concerning leprosy vary in the different states. New York, for example, has no stringent laws and there are 40 or 50 cases at large in New York City. Pennsylvania and Massachusetts, on the other hand, enforce strict segregation.

made up almost exclusively of imported cases, another among the Orientals on the Pacific Coast, likewise chiefly of imported cases, and the third on the Gulf Coast, particularly in Louisiana, Texas and Florida, where most of the cases are native born. According to the most recent figures available (1914) the number of cases in isolation in our insular possessions is as follows: Hawaii, 643; Porto Rico, 28; Philippine Islands, 4,629; the Canal Zone, 7. The lepers in Guam, 18 in number, were transferred to the Philippine leper colony at Culion during 1913. It is known, however, that everywhere that the disease prevails many cases escape tabulation in the official returns. There are perhaps a million lepers in the world. About 50 per cent. more males are affected than females.

The cause of leprosy is the *Bacillus leprae* discovered by Armauer-Hansen in 1874. The bacillus of leprosy resembles the bacillus of tuberculosis in many, though superficial, respects. It stains more readily and decolorizes somewhat more readily than the tubercle bacillus, but differential staining reactions are not trustworthy. It differs from the tubercle bacillus in that it grows with difficulty on artificial culture media in primary cultures and is not pathogenic for the lower animals. Further, lepra bacilli are usually found in dense clusters and in much greater numbers within the cells than is the case with the tubercle bacillus.

The bacillus of leprosy grows with difficulty upon artificial culture media. For years it has evaded all attempts until Clegg<sup>52</sup> in 1909 succeeded in cultivating an acid-fast bacillus in symbiosis with amebae and cholera vibrio upon plain agar and weakly nutrient agar. Clegg based his work upon the belief that the leprosy bacillus derives its nutrition from the products of the tissue cells in which it is mainly to be seen in leprosy lesions. These results have been confirmed by Currie, Brinkerhoff, Holmann and McCoy in Hawaii and by Duval in New Orleans.

The latter has shown that the amebas are not essential and that other microorganisms may replace the cholera vibrio or that the addition of certain amino-acids (tryptophan and cystein) to the media is sufficient to bring about the necessary conditions for growth. There is no satisfactory evidence that any of the cultures isolated will reproduce the disease in experimental animals.

**Immunity.**—There is no racial immunity to leprosy. The white races suffered severely during the middle ages. Malays, Mongols and Negroes now appear most liable to the infection, perhaps on account of their mode of life. The disease is remarkable for its prolonged period of incubation and its chronic course. The lesions may not be noticed until 20 or more years after exposure. The disease is not usually recog-

<sup>52</sup> *The Philippine Jour. of Science*, Vol. IV, No. 77, Apr., 1909. *Public Health Bull.* No. 47, Sept., 1911.

nized until several years have elapsed. These facts indicate that the body must possess a high degree of resistance to this infection. So far as known, man is the only animal subject to leprosy under natural conditions. Inoculation experiments into lower animals have recently been reported in the guinea-pig (Clegg); the Japanese dancing mouse (Sugai); and the monkey (Duval). It is questionable, however, whether the disease has been reproduced in the lower animals.

Leprous material has been inoculated into human beings by Danielson, Profeta, Cagnina and Bargilli with negative results. These experiments demonstrate the resistance of the body to the virus. In Arning's well-known case of the convict Keanu, who was pardoned on condition that he allow himself to be inoculated with leprosy, the disease did develop, but the experiment is somewhat spoiled by the fact that the man lived in a leprosy focus and had lepers among his relatives.

**Rat Leprosy.**—There is a disease among rats which is a close counterpart of leprosy in man. It occurs naturally in the *Mus norvegicus* and may be transferred by inoculation to the more tractable laboratory white rat. The disease was first observed by Stenfansky in 1903 in Odessa. In the same year Rabinowitsch found the disease among the rats of Berlin, and Dean in 1903 discovered the disease independently in London, and in a later publication (1905) reported success in transferring the infection by artificial inoculation. Since then rat leprosy has been found by Tidswell in the rats of Sydney, Australia; by Kitasato in Japan; Marchoux and Lebœuf in Paris, and the English Plague Commission observed the disease among the rats in India. Wherry and McCoy found a number of cases among the rats caught in San Francisco, California.

The proportion of rats infected with rat leprosy in different localities varies greatly; thus in Odessa and Paris from 4 to 5 per cent., in San Francisco 0.2 per cent., and in Sydney only 0.001 per cent. Currie failed to find leprosy among the rats of Honolulu. The fact that the infection is absent among the rats of Honolulu and present among the rats in Berlin is evidence that it plays no part in the epidemiology of the human disease.

Leprous rats in a late stage of the disease are usually recognized by the presence of patchy alopecia associated with cutaneous and subcutaneous nodules which may be the site of open ulcers; only in advanced cases are the internal organs affected. The diagnosis is readily confirmed by microscopic examination of a smear from an ulcer or a nodule, which will show the acid- and alcohol-fast bacillus of the disease in enormous numbers, and mostly in the cells.

Currie has shown that rats may infect each other by contact, also that bacilli of rat leprosy may often be demonstrated in the heart's blood of infected rats. Currie and also Marchoux and Sorel had

no difficulty in demonstrating the presence of acid-fast bacilli in mites contained on the bodies of rats when the latter's heart's blood contained the microorganisms. The fact that these mites so frequently contain the bacilli naturally leads to the suspicion that they may be one of the means of transmitting the disease from rat to rat, but up to the present time no positive evidence has been adduced that such is the case.

Mezincescu, using rat leprosy antigen, obtained complete complement fixation with human leprosy serum; this confirmed Slatineau's work. Schmitt obtained positive results with syphilitic antigen and human leprosy serum, and numerous other observers have, with different antigens and serum, obtained positive reactions and thus have shown the similarity of the two diseases. The bacillus has been cultivated by Dean, Hollman, Chapin, and others.

In this leprosy-like disease of rats we have an infection which closely resembles leprosy in man. The fact that the infection may be propagated in a laboratory animal permits of its investigation, and it is hoped that further studies upon rat leprosy will throw light upon the modes of transmission and control of the human disease.

**Modes of Transmission.**—The leprosy bacillus is found in all the lesions of the disease—the nodules on the skin and mucous membranes, in the spleen, liver, and testicles—in fact, in all the internal lesions. In the anesthetic type the bacilli are found in the cells of the spinal cord and brain and also in the peripheral nerves. Leprosy bacilli may also be found in the circulating blood during the febrile attacks. Frequently they are in the endothelial or in the white blood cells. The leprosy bacillus leaves the body from any of the lesions that are broken down. From the degenerated nodules of the skin or mucous membranes they are discharged in enormous numbers. If we may depend upon microchemical evidence, it appears that most of these bacilli are probably dead. Leprosy bacilli also occasionally appear in the feces and urine. They occur in the expectoration from lesions in the throat which are common.

There is some doubt as to just how the leprosy bacillus enters the body, whether through wounds of the skin or through the mucous membrane of the nose and throat or through the digestive tract, or possibly during coitus. Insects are also suspected.

It may be definitely stated that leprosy is not due to the eating of any particular food, such as fish. This theory has been stoutly maintained by Jonathan Hutchinson. There is no satisfactory evidence in support of the fish theory and many facts against it. One thing is plain, and that is, leprosy is not contracted from any of the lower animals, but is an infection which in all cases passes rather directly from man to man.

The suspicion that parasitic insects may play some rôle in the transmission of leprosy has existed for some time. The evidence is reviewed

by Nuttall,<sup>53</sup> who says: "It appears that Linnæus and Rolander considered that *Chlorops (musca) lepræ* was able to cause leprosy by its bite." Blanchard and Corrodor tell of flies in connection with leprosy. Flies frequently gather in great numbers on the leprosy ulcers and then visit and bite other persons. An observation by Boeck of the presence of *Sarcoptes scabiei* in a case of cutaneous leprosy led Joly to conclude that these parasites might at times serve as carriers of the infection. Pediculi are usually present among the poor classes in Algeria, which furnish the greater number of lepers. Sommer of Buenos Aires expresses the belief that mosquitoes act as active agents in the spread of leprosy in warm countries. Carrasquillo of Bogota found the bacillus of Hansen in the intestinal contents of flies. The British Leprosy Commission investigated the possible rôle played by insects with entirely negative results. Wherry studied the occurrence of lepra-like bacilli in certain flies and their larva. He found that the fly *Chlorops vomitoria* took up enormous numbers of lepra bacilli from the carcass of a leper rat and deposited them with their feces, but the bacilli apparently do not multiply in the flies, as the latter are clear of bacilli in less than 48 hours. Larvae of *Chlorops vomitoria* hatched out in the carcass of a leper rat become heavily infested with lepra bacilli. If such larvae are removed and fed on uninfected meat they soon rid themselves of most of the lepra bacilli. A fly, *Musca domestica*, caught on the face of a human leper was found to be infested with lepra-like bacilli. The horrid sight of flies swarming about leprosy lesions and the nostrils of leprosy beggars is well-known to travelers in eastern countries. Lepra-like bacilli have been found in bedbugs and these insects have long been associated with the spread of the disease.

The evidence bearing on the possible rôle of insects in the transmission of leprosy may be classified as purely presumptive evidence based upon analogy, or as evidence based simply upon the finding of acid-fast bacilli in certain insects. It must be plain that the simple taking up of parasites by an insect does not necessarily imply that the insect plays a rôle in its transmission from one host to another. Further, not all acid-fast bacilli are leprosy bacilli. It cannot be denied that leprosy may be one of the insect-borne diseases; the final verdict will depend upon further studies.

A great majority of lepers at some time in the disease have lepra bacilli<sup>54</sup> in their nasal secretions. The importance of the nose in leprosy was brought into prominence at the First International Leper Conference in 1897 by the work of Sticker, who made sweeping statements concerning the nose as the site of the primary lesion and the danger

<sup>53</sup> *Johns Hopkins Hospital Reports*, 1900, VIII, p. 1.

<sup>54</sup> Acid-fast bacilli, resembling the bacillus of Hansen are called "lepra bacilli." There are many acid-fast bacilli, and we have no clear criterion to differentiate the bacillus of leprosy.

of nasal secretions in transmitting the disease. Jeanselme and Laurans (1895), Gerber (1901), Werner (1902), Sheroux (1903), and others have shown the frequency with which the bacilli of leprosy appear in the nasal secretions and the importance of the nose as a site of leprosy lesions. Sticker cites a five-year-old child of leprosy parents seen by him in India with an ulcer on the right side of the nasal septum which contained lepra bacilli and was the only lesion of the disease present in the case. Plumert (1903) mentions the finding of lepra bacilli in the nasal secretions of persons in intimate family contact with advanced cases of leprosy. The individuals in question showed no other evidence of the disease. Falkao observed epistaxis associated with small ulcers on the nasal septum of descendants of lepers, and lepra bacilli were found in the crusts from these ulcers. The results of Sticker, Plumert, and Falkao would indicate that in the early stages of the disease the nose is frequently the site of a lesion discharging lepra bacilli. Brinckerhoff and Moore, however, who made a careful study of this question in Honolulu, point out that most of the studies upon the importance of the nose in leprosy have been made upon relatively advanced cases of the disease. They found the nose frequently the seat of infection when the disease is well developed, but practically never as a primary or incipient lesion. If the nose were the usual seat of the primary lesion in leprosy, it might indicate that the infection is carried there upon the finger.

Holmann studied 500 persons in the Hawaiian Islands suffering with a recognizable form of leprosy for periods varying from three months to twenty-five years, and found 410 with lesions of the nasal mucous membrane and only 90 in which such lesions were absent.

Bearing upon the contagiousness of leprosy we have Kitasato's statistics from Japan showing that the children of lepers become leprosy in a proportion of only 7.05 per cent. of the total. Matrimonial infection was proved in 3.8 per cent. of cases, while persons living under the same roof showed a proportion of only 2.7 per cent. Brothers and sisters infect each other in a ratio of 4.2 per cent. These figures roughly correspond to Sand and Lies' studies in Norway. It is a common observation that elderly persons are less likely to become infected with the disease than young persons.

Jeanselme<sup>55</sup> reports observations confirming the Chinese and Japanese belief that leprosy spreads largely by sexual contact. Jeanselme found "leprosy" urethritis set up by lepromata which invaded the navicular fossa. He further states that myriads of acid-fast bacilli may be found in a drop of pus which may be squeezed from the meatus under this condition.

It is sufficient for practical prevention to know that leprosy is spread

<sup>55</sup> *Bull. de la Société de Médecine Exotique*, No. 7, 1914.

mainly by direct contact and perhaps occasionally by indirect contact with persons suffering with the disease. In a case observed in northern Germany one girl directly and indirectly infected 28 people. Leprosy is most prevalent under conditions of personal and domestic uncleanness and overcrowding, especially where there is close and protracted association between the "clean" and the "unclean." There are instances on record in which persons have contracted the infection after a stay of only a day or two in a leprous-ridden area. There is no evidence that leprosy is inherited. Children born of leprous parents do not as a rule develop the disease if removed at once. The occurrence of several cases in a single family is doubtless due to "contact." The danger of infection from leprous persons is, of course, greater when there is a discharge from the lesions of the skin and mucous membranes.

**Prevention.**—The prevention of leprosy depends almost entirely upon isolation, care of the infected discharges, personal cleanliness, and sanitary surroundings. The disease is transmitted with difficulty; however, doctors, nurses, sisters of charity, ward tenders, and others directly exposed in leprosaria sometimes become infected. Notable examples have been Father Damien at Molokai, Hawaii, Father Bogliolo in New Orleans, Sir George Turner in Pretoria, and Miss Mary Reed in India. About 5 per cent. of the healthy consorts of lepers become infected at the Hawaiian settlement. Evidently close, prolonged and intimate contact is ordinarily necessary to contract the infection.

For the control of leprosy the most important administrative measure is to segregate the lepers in settlements or asylums. Segregation also entails proper treatment and humane care. Compulsory notification of every case of leprosy should be enforced, if for no other reason than to keep track of the disease and to know whether it is on the increase. The leprosaria should be inviting and should contain all modern improvements for the care and treatment of the disease. Leprosy is by no means invariably fatal. In the United States, where there are only a few hundred lepers, the Government has provided for the establishment of a national leprosarium which is located at Carville, Louisiana. To require each state to provide suitable accommodations to segregate its few lepers is economically wasteful.

It is claimed that the decrease in leprosy in Europe during the middle ages was due in large part to the segregation of the lepers in leprosaria, which at one time numbered 20,000. On the other hand, the value of segregation is disputed because many lepers were at large; however, they were not allowed in churches or market places, and were branded as "unclean" by a distinctive dress and were further required to make their presence known by a bell or clapper. Great numbers of lepers were swept away by the bubonic plague during these times. As a rule, only the advanced cases are detected and isolated. In some of the

British colonies in South Africa, where only about half of the leper population is segregated, the rate of admission has remained constant for the last ten years. Segregation in the Hawaiian Islands and the Philippines probably has so far had no conspicuous effect upon the prevalence of the disease; the results are the subject of controversy. There are factors in the control of leprosy not yet understood. As soon as a country becomes well to do and adopts the daily tidiness incident to modern civilized life, leprosy dies out.

There can be little objection in a country such as ours, where leprosy shows slight tendency to spread, to give a clean leper his freedom, except in the endemic foci in the Gulf States and elsewhere. There is no more danger from a leprosy patient with clean personal habits, who exercises care concerning the discharges from the lesions, than there is from an open case of tuberculosis of the glands of the neck. The purely nerve cases, particularly if there are no ulcerations, may properly be given a greater degree of liberty than those with nodular manifestations.

The national quarantine regulations forbid the landing of an alien leper. The law requires that such person be deported on the same vessel that brought him. A citizen of the United States having leprosy cannot be debarred. Such individuals are admitted and then come under the health laws of the state or port of entry.

**Specific Prevention.**—There is no specific prevention or cure for leprosy. Surgical cleanliness and frequent dressings help check the spread of the infection. Nastin is a substance proposed by Deycke and consists of a neutral fat obtained from a streptothrix. The reports from its use are not particularly encouraging. Rost, of Rangoon, Burma, uses a substance which he calls "leprolin," a precipitate from leprous tubercles. A large proportion (75 to 80 per cent.) of lepers give a positive Wassermann reaction (independent of syphilis), but not the luetin reactions. Tuberculin in somewhat large doses injected subcutaneously into leprous patients produces both a general and local reaction, but the repeated injections do not materially influence the disease, although such treatment seems to cause a local improvement or softening of the leprous tubercles. Heiser, in Manila, reports favorable local results from the application of X-rays. Chaulmoogra oil and Gurjun balsam have been extensively used. Rogers, in India, has recently reported encouraging results from the subcutaneous and intravenous use of gynocardate of sodium, a derivative of chaulmoogra oil. McDonald and Dean<sup>56</sup> in Hawaii have reported good results from ethyl esters of chaulmoogra oil. Many observers report improvement from good food, fresh air, cleanliness, and the general principles applicable to the modern treatment and prevention of tuberculosis.

<sup>56</sup> *Public Health Reports*, No. 34, XXXV, 1919.

In appraising the influence of treatment it must be borne in mind that leprosy is prone to prolonged periods of quiescence and that marked improvement often occurs spontaneously, and indeed that this may go on to apparent cure.

## SECTION II

### MENTAL HYGIENE

BY THOMAS W. SALMON, M.D.

*Medical Director, National Committee for Mental Hygiene; formerly  
Passed Assistant Surgeon, U. S. Public Health Service; formerly  
Chairman, New York State Board of Alienists.*

A very few years ago it would have been difficult to justify the inclusion of a chapter on mental hygiene in a general treatise on preventive medicine and hygiene. The medico-legal term "insanity" was used to designate all abnormal mental states and the incorrect conception of mental and physical diseases as distinct and practically unrelated was widely accepted. These misconceptions and the hopelessness, both as to cure and prevention, which characterized the medical attitude toward mental diseases combined to disassociate mental medicine and its problems from the subjects which were engaging the attention of physicians and sanitarians generally. There seemed little likelihood that the determination to prevent diseases which was beginning to dominate the medical profession would soon extend into the domain of mental medicine. Today, however, a treatise on the prevention of disease which failed to include a chapter on mental hygiene would neglect an important field of preventive medicine. The realization that many forms of mental disease depend in a large measure upon preventable causes, the rapid growth of psychiatry and its acceptance as a department of scientific medicine, and the newly discovered opportunities for utilizing its resources in practical attempts to deal with social problems have broken down the barriers which so long and so effectually isolated mental medicine.

It is not easy to present even the main facts of mental hygiene within the limits of a single chapter, for it is not sufficient to discuss some of the more important preventable or modifiable causes of mental diseases and mental deficiency and to outline some of the means which may be employed in their control. Hygiene deals with measures which promote health as well as with the prevention of disease and it is necessary, in any useful presentation of the essentials of mental hygiene, to consider to what extent some of the mental factors which interfere

<sup>1</sup> In the first edition this chapter was called "The Prevention of Mental Diseases," but the prevention of mental diseases is a relatively small part of the field of mental hygiene. Therefore, in this edition both the title and the scope of this chapter have been changed to "Mental Hygiene."

with the successful adaptation of the individual to the environment can be favorably modified. It is clearly within the sphere of mental hygiene to strive to prevent those failures of adaptation which, while they may never bring about the graver disturbances of adjustment which we term mental diseases (psychoses), may, nevertheless, distort the life and profoundly impair the efficiency and happiness of the individual.

### THE PROBLEMS OF MENTAL HYGIENE

**Number of Insane and Mental Defectives.**—On January 1, 1920, there were 232,680<sup>2</sup> patients with mental diseases in hospitals for the insane in this country. If the number on parole from these hospitals is included, the total number of patients with mental diseases under supervision of these hospitals on that date was over 250,000—a number almost equal to the number of students in all the colleges and universities in the United States, and exceeding the population of Toledo, Ohio, our twenty-sixth city in size. This great number by no means included all persons with mental diseases in this country or even the number who would have been receiving treatment in hospitals on January 1, 1920, had all the states supplied adequate provisions. We know that the ratio of persons with mental diseases to the whole population is about the same in different parts of the country, for wherever sufficient institutional provisions exist they are utilized to very much the same extent. If, therefore, all the states provided for the insane as adequately as do Massachusetts and New York, there would have been more than 350,000 patients in institutions on January 1, 1920, instead of 232,680. The cost of caring for mental diseases in a state which makes adequate provisions exceeds any single item of expense except that for public education. The average annual cost of caring for a patient in a state hospital for the insane is about \$250, making the total yearly cost of caring for the 200,000 patients under treatment in state hospitals alone more than \$50,000,000. To this great sum should be added, if we are to state fairly the cost of mental diseases, the economic loss through the withdrawal from active life of more than 60,000 people who enter these hospitals each year.

No one can state the number of the mentally defective in this country or even the number requiring institutional care. Massachusetts, the state which has supplied institutional provisions most liberally, has one bed to every 1,248 of the general population for such sufferers.<sup>3</sup> If this ratio existed in every state there would be 84,682 mental defectives

<sup>2</sup> Pollock, H. M., and Furbush, Edith M.: "Patients with Mental Disease, Mental Defect, Epilepsy, Alcoholism and Drug Addiction in Institutions in the United States, January 1, 1920." *Mental Hygiene*, V, Jan., 1921.

<sup>3</sup> Not including epileptics.

in state institutions at the present time. Actually there are approximately 35,000.<sup>4</sup> We know, however, that even in the state which has made the most liberal provisions there are many mentally defective persons uncared for and many who are improperly confined in correctional institutions or in almshouses. There is reason to believe that there are no less than four mentally defective persons in every thousand of the whole population. Although their cost to the communities through their own dependence, the support of their illegitimate children, and the crimes and misdemeanors which they commit, or more frequently invite, cannot be estimated, we know that it is more even than the great cost of caring for them in suitable institutions would be.

**Scope of Subject.**—Such statistics as these serve as a convenient means for comparing the cost of mental diseases and mental deficiency with that of other diseases, but they cannot convey an adequate idea of the personal suffering and unhappiness and the social and family disasters for which mental disorders are directly responsible. It should be remembered that the same causes which bring about the commitment of many thousands of persons as “insane” each year are responsible for much mental disease which is never recognized and for many failures in adaptation which prevent people from meeting difficult situations in life and which lead to innumerable conflicts with laws and conventions. To avert some of these disasters is as much the task of mental hygiene as to control the preventable causes of mental disease and of mental deficiency. With these considerations in mind, some of the causes of mental diseases, mental deficiency, and other abnormal mental states will be briefly stated. Measures of prevention which seem applicable will be considered while discussing each cause, and the more general causative conditions and more general measures for preventing mental disease and promoting mental hygiene will be taken up last.

**Definitions.**—In the pages which follow, the term *psychoses* refers to mental diseases, or “forms of insanity” as they are more familiarly but less accurately called. Dr. William A. White has pointed out the enormous advantages of restricting the use of the term “insane” to that group of persons who suffer from civic disabilities of one kind or another (commitment to institutions, testamentary incapacity, incompetency to use property, etc.) because of legal proceedings necessitated by mental diseases.

*Insanity* thus becomes a strictly legal term, with which physicians and sanitarians are concerned only when medico-legal or certain social phases of mental diseases are under consideration. Persons with mental

<sup>4</sup>Pollock, H. M., and Furbush, Edith M.: “Patients with Mental Disease, Mental Defect, Epilepsy, Alcoholism, and Drug Addiction in Institutions in the United States,” January 1, 1920. *Mental Hygiene*, V, Jan., 1921.

disease may or may not be "insane." The term insanity will be used here only in this medico-legal sense.

The term *mental deficiency* will be used to designate the various types and degrees of mental defect (idiocy, imbecility, feeble-mindedness, psychopathic inferiority, etc.) existing at birth or arising during the early period of development.

The term *psychoneuroses* will be used to designate the group of functional nervous diseases that includes neurasthenia, hysteria, anxiety states and various conditions loosely designated by the laity as "nervous breakdowns."

It is not possible to find a single word with which to designate those minor interferences with mental health or with mental efficiency which underlie many such difficulties of adaptation as those which have been mentioned.

### HEREDITY

**Psychoses.**—The accepted theories of heredity and the general relation of heredity to disease have been considered elsewhere (Section IV, Chapters II and III, page 607). In examining the relation of heredity to mental diseases, the advantage of dropping the use of the medico-legal term "insanity" is apparent, for statistical studies indicate that in some mental diseases heredity is a factor of the utmost importance, while in others it apparently influences causation very little if at all.

Rosanoff and Orr<sup>5</sup> concluded from a study of inheritance in 73 cases of mental diseases, representing 206 different matings and 1,097 offspring, that this common basis, which they designated the "neuropathic constitution," is inherited in accordance with Mendel's law. They believed the neuropathic constitution to be a trait which is recessive to the normal and, furthermore, that various clinical neuropathic manifestations bear to each other the relationship of traits of various degrees of the recessive; that is to say, neuropathic traits which are recessive compared with normal traits are at the same time dominant over other neuropathic traits. The degree to which neuropathic traits are recessive seemed to Rosanoff and Orr to conform in general to the severity of the type of psychosis or neurosis. Unfortunately, these findings alone are not sufficient evidence upon which to base general conclusions as to the relation between heredity and mental diseases. The study of the inheritance of mental diseases presents many complex problems and many special difficulties, not the least of which is that the field work upon which it depends so greatly cannot be entrusted to workers who have not had psychiatric training. Dr. E. Rüdin of Munich has made very careful studies

<sup>5</sup> Rosanoff, A. J., and Orr, Florence I.: "The Study of Heredity in Insanity in the Light of the Mendelian Theory. *Bulletin No. V, Eugenics Record Office.*

of inheritance in mental diseases, his investigations being particularly valuable because he performed the actual field work himself. In a communication summing up his findings from 1909 to 1911, he stated<sup>6</sup> that he felt that he had not done enough work to justify the formulation of laws regarding the hereditary factors of mental diseases. Scientific study of this subject is being carried on actively and it seems desirable, at the present time, to reserve judgment as to the conflicting findings which are being presented.<sup>7</sup>

If the precise part played by inheritance in the causation of mental diseases cannot be stated, it should not be thought that evidence is lacking to show its importance. It is probably safe to say that heredity is responsible, directly and indirectly, for more cases of mental disease than any other single cause. In about 50 per cent. of all admissions to hospitals in which careful records are made and scientific study of cases is carried on, the history of mental diseases in other members of the family is found. There are no statistics in this country to show the percentage of normal persons in whose families the history of mental disease is found, but studies elsewhere have shown it to be from 3 to 7.5 per cent.

*Effect of Environment.*—Neuropathic heredity exercises powerful indirect influences through the unfavorable environmental influences in which the children of psychotic parents are compelled to spend their developmental years. Distorted views of life, queer religious and political beliefs and various antisocial attitudes on the part of such parents mold the mental reactions of their children and even when no direct hereditary tendency is transmitted such children suffer through having their education interfered with and their capacity for social adjustment restricted. In some cases they acquire and firmly hold false beliefs which, on the part of their parents, were actually delusional.

**Mental Deficiency.**—In mental deficiency we have one of the best examples of a pathological condition directly transmitted by inheritance. Although the same type of neuropathic heredity which is met so often in the psychoses is found more frequently in the mentally defective than in normal persons, mental deficiency depends chiefly upon a more *specific* kind of inheritance—the direct transmission of the same condition. Goddard<sup>8</sup> found, in 300 family histories in which the data were regarded as satisfactory, that 54 per cent. showed mentally defective relatives “in such numbers or in such relations to the individual case studied as to leave no doubt of the hereditary character of mental defect.”

<sup>6</sup> Rüdin, E.: *Zeitschrift für die Gesamte Neurologie und Psychiatrie*, Vol. 7; Part 5, November 18, 1911.

<sup>7</sup> The reader who is interested in this phase of mental hygiene will find an excellent bibliography, after Rüdin, in “Some Problems in the Study of Heredity in Mental Disease” by Dr. H. A. Cotton. *American Journal of Insanity*, July, 1912.

<sup>8</sup> Goddard, H. H.: “Feeble-mindedness,” 1915, p. 436.

He considered 11.3 per cent. of the remaining cases in this series as "probably hereditary." Other studies have, unfortunately, grouped mental deficiency, mental diseases and epilepsy in estimating the hereditary factors in mental deficiency. Tredgold<sup>9</sup> found, in a series of 200 cases in which he very carefully investigated the family histories, that 64.5 per cent. had mental deficiency, mental diseases, or epilepsy in their ancestry. Lapage<sup>10</sup> found the same conditions in the families of 48.4 per cent. of the children in the special schools of Manchester, and Potts<sup>11</sup> found 45.6 per cent. in the families of children in similar schools in Birmingham.

In Tredgold's series of 200 cases, a marked predisposition to paralysis, cerebral hemorrhage and various neuroses existed in 18 per cent., making the proportion in which either a mentally defective or neuropathic heredity was found 82.5 per cent. Goddard found epilepsy, insanity, blindness, and deafness (which he grouped under the term "neuropathic ancestry") in 12 per cent. of his series. It is most unfortunate that different methods of grouping neuropathic conditions should be employed by different investigators, for it makes it impossible to compare their results. It is also unfortunate that widely different conditions should be included in the same group. Certainly blindness and insanity must represent very different types of heredity in Goddard's cases, while cerebral hemorrhage and the neuroses are equally incongruous members of the same group in Tredgold's series.

There is need for much more intensive study of heredity in mental deficiency, especially in those cases in which neuropathic inheritance and not mental deficiency is found in the progenitors. Even in the large proportion of cases in which mental deficiency seems to be transmitted directly, it is desirable to know the relation of heredity to the different types and grades of mental deficiency. As a step in this direction, Goddard has pointed out that his series seemed to indicate that low-grade cases come from families with the least amount of mental defect. In the interpretation of this interesting fact, the barriers to reproduction which exist among low-grade defectives, their high mortality rate before puberty and the excessive prevalence among them of severe organic lesions of the brain, many of them accidental or syphilitic, must be taken into account.

The *relation of heredity to mental deficiency* is a matter of the greatest importance on account of its bearing upon prevention. The general fact that mental deficiency depends chiefly upon inheritance having been well established, it seems most essential now to study heredity *specifically*, as we do in the psychoses—that is, with reference

<sup>9</sup> Tredgold, A. F.: "Mental Deficiency," 1914, p. 40.

<sup>10</sup> Lapage, C. P.: "Feeble-mindedness in Children," 1911.

<sup>11</sup> Potts, W. A.: *British Journal of Children's Diseases*, March, 1909.

to particular types and grades. If the judicial authorities are to be asked to commit a mentally defective person to an institution for life solely because of the danger of transmitting his defect to others, they have a right to ask what is known beyond reasonable doubt regarding the hereditary factors in *that particular case* and in *that particular type* of mental deficiency. It is quite certain that they will look with suspicion upon long-distance diagnoses by inexperienced investigators and yet it is upon precisely that kind of diagnosis that much of the information which we are making widely known today depends. In determining the heredity of a given case much depends upon establishing the existence of mental defect in many living persons not in institutions and in others long since dead. Many field workers engaged in such studies are poorly equipped by training to diagnose mental deficiency even in a formal examination, with all the aids available for such work, and some of them are quite inexperienced in estimating the significance of various types of antisocial conduct. It has been said in justification of some rather questionable findings of such workers that physicians conclude upon evidence "infinitely weaker" that Napoleon, Julius Cæsar, and Saint Paul were epileptics. Without considering the striking outward manifestations of epilepsy, it should be said that extensive medical notes by Napoleon's physicians are in existence and that the data regarding Julius Cæsar upon which the existence of epilepsy is assumed are not much less trustworthy than those available regarding some obscure feeble-minded persons who died fifty or more years ago. It is to be remembered, however, that the diagnoses of the maladies of great historical characters which are offered from time to time by physicians are presented merely as interesting surmises, not as scientific data upon which to base an extensive program of legislation and institutional provision.

It is of much practical importance, with reference to prevention, to know if hereditary mental deficiency is transmitted in accordance with definite laws. Goddard's investigations showed a correlation between the actual findings and the proportion of mental defectives which, theoretically, should occur in the 324 matings of different types in his series if mental deficiency is transmitted in accordance with Mendel's law to justify him in saying that "such results are difficult to account for on any other basis than that feeble-mindedness is transmitted in accordance with the Mendelian formula."

The part played by heredity in the production of the psychoneuroses is not very clearly established. An important contribution to the subject was made by Dr. Julian M. Wolfson<sup>12</sup> who ascertained that a neuro-pathic heredity existed in 10 per cent. of a group of 100 British soldiers

<sup>12</sup> Wolfsohn, Julian M.: "The Predisposing Factors of War Psychoneuroses." *The Lancet*, Feb. 2, 1918.

in the Fourth London General Hospital who were suffering from wounds and in 72 per cent. of a group of 100 soldiers in another department of the same hospital who were suffering from war neuroses. In the psychoneuroses in civil life it is certain that a neuropathic heredity is more commonly found than among persons who do not suffer from these disorders, but there are many individuals who suffer severely from various psychoneurotic difficulties whose parents and brothers and sisters apparently have no such disorders.

**Preventive Measures.**—This is the domain of eugenics, a subject which is considered elsewhere in this volume (Section IV, Chapter II). In considering measures for controlling the inheritance of the neuropathic constitution the caution contained in the following statement by Adolf Meyer<sup>13</sup> may well be borne in mind: "In such a matter as the prevention of mental trouble due to heredity, I maintain that, although we know that a large percentage of mental cases have a history of heredity, there is not a sufficiently decisive body of facts established for us to be justified in making sweeping rules against the marriage of those who have had mental troubles either themselves or in their families. Indeed, we might thereby run the risk of doing a grave injustice to the race as well as infringing on the rights of the individual."

In the case of hereditary mental defect there can be no question that the right of the individual to bear children must be disregarded in the interests of ordinary humanity as well as in the interests of the race. The questions of the sterilization and segregation of the defective and the regulation of marriage are considered elsewhere, but it should be said here that in not a few mentally defective persons there is an alternative to segregation in an institution for life. It is possible to devise a system of safeguards which, with registration and commitment to guardianship if necessary, will make a supervised life in the community safe for a very carefully selected number of such individuals. The establishment of such a system of supervision and registration is one of the great constructive tasks which must be undertaken if we are to deal with the problem of the mentally defective in the most humane and effective manner possible.

Few people would care to say that persons having psychoneurotic disorders should not marry, or, if they do marry, should refrain from having children, and yet it would be certainly wise for a physician, if consulted, to advise against the marriage of two persons both of whom had had important psychoneurotic episodes or who showed evidence of psychoneurotic make-up.

<sup>13</sup> Meyer, Adolf: "Organizing the Community for the Protection of Its Mental Health." *The Survey*, September 18, 1915.

## ALCOHOL

**Psychoses.**—In discussing alcohol as a cause of mental disease it is very desirable to indicate whether it is being considered as a direct cause or as one of several etiological factors. Alcohol is the *essential cause* of the alcoholic psychoses, those mental diseases which from their symptoms, pathology, or course we have come to recognize as due directly to alcohol. In these disorders—*Korsakow's disease, alcoholic hallucinosis, delirium tremens, alcoholic deterioration*—to diagnose the condition is to know the cause. Other causes, such as trauma and disorders of nutrition, doubtless contribute in many cases and in a very large proportion of cases the neuropathic constitution underlies the habit of alcoholism, but whatever other mental diseases these patients might some time have, they could not develop these particular psychoses without the intemperate use of alcohol.

The alcoholic psychoses account for about 4 per cent. of all first admissions to hospitals for the insane. They occur about three times as frequently in men as in women and, in general, more frequently in admissions from cities than from rural districts. This difference in the environment of admissions for alcoholic psychoses is much more striking in the case of women than in men.<sup>14</sup>

It is difficult and perhaps impossible to estimate the influence of alcohol in the causation of other psychoses. Of the cases in which a satisfactory history as to alcoholic habits was obtained in the patients admitted to the New York State hospitals during 1919, about 16 per cent. were intemperate. Excluding the alcoholic psychoses, the prevalence of intemperance among the more important psychoses is shown by the following table:

Psychoses	Per Cent. Intemperate
Senile psychoses	13.0
General paresis	23.9
Psychoses with cerebral arteriosclerosis	15.5
Dementia praecox	9.6
Paranoia and paranoid conditions	12.5
Epileptic psychoses	10.8
Manic-depressive	6.0

(From New York State Hospital Commission report for year ended June 30, 1919.)

<sup>14</sup>There has been a steady fall in the percentage of admissions with alcoholic psychoses during recent years. This may be partly accounted for by better distribution of cases formerly thought to be alcoholic psychoses but it is possible that it is due in part to the growing temperance movement.

No statistics are available to show the extent of intemperance among adults in the community generally; nevertheless it seems very likely that it is much less than in even the psychoses showing the least frequency. Many elements have to be taken in consideration in interpreting these percentages, especially the fact that defects in judgment and relaxation of inhibitions due to mental disease lead to intemperance, as they do to other disorders of conduct. It is significant, therefore, that general paresis shows the highest percentage of intemperance. The seclusiveness of persons with paranoid tendencies and dementia praecox and the low percentage of alcoholism in these disorders may bear some relation to the influence of conviviality upon intemperance.

In many individual cases there is abundant evidence that intemperance plays a prominent part in the psychoses which are not primarily dependent upon alcohol. The effects of alcohol in producing excited episodes in the mentally defective is well known and intemperance lends a tremendous impetus to the retrogressive changes in senility. As a result of greatly increased attention being directed to the alcoholic psychoses, interesting facts are being brought out. It has been shown by Pollock<sup>15</sup> in a study of 464 cases of the alcoholic psychoses that the average duration of intemperance before the onset of the psychosis was 20.6 years. As will be seen, this fact has an important bearing upon prevention. It does not seem amiss to point out here the misleading impression which is given by the statement often made that alcohol is "filling our hospitals for the insane." The alcoholic psychoses are of comparatively short duration; the recovery rate is more than 50 per cent.; hence the number of patients with these diseases under treatment at any time is always less than the annual admission rate of these diseases. Such statements made by enthusiastic temperance advocates injure a splendid cause for the exaggerated estimates given make it impossible to show the expected reduction in the number of patients in the hospitals of prohibition states after prohibition has gone into effect, thus providing the enemies of prohibition with arguments in advocacy of license.

**Mental Deficiency.**—Statistics regarding alcohol as a cause of mental deficiency deal wholly with the influence which intemperance in the parents is said to exercise. The data available, while abundant, are very unsatisfactory and have to be interpreted with especial care on account of the fact that the alcoholic parents whose habits are so often thought to have been responsible for mental deficiency in their children were sometimes also mentally defective and in reality transmitted their defect directly. Tredgold states that a family history of alcoholism was present

<sup>15</sup> Pollock, Horatio M.: "The Use and Effect of Alcohol in Relation to the Alcoholic Psychoses." *New York State Hospitals Bulletin*, V, 8, pp. 264-79, August, 1915; also, *Psychiatric Bulletin*, V, 2, April, 1917.

in 46.5 per cent. of the series of 200 cases which he studied carefully, but that no less than five-sixths of these cases with an alcoholic parentage also had a well-defined neuropathic inheritance. He believes that paternal or maternal alcoholism may produce mental deficiency in the offspring without other cause, but that this is rare. In a very interesting chapter, Goddard discusses the alcoholics (drunkards) among the parents in his series of cases and concludes that "everything seems to indicate that alcoholism itself is only a symptom, that it for the most part occurs in families where there is some form of neurotic taint, especially feeble-mindedness." He points out that if alcoholism were responsible alone for mental deficiency there would doubtless be much more mental deficiency than there is, especially in view of the great prevalence of drunkenness among all classes only a few generations ago.

Intemperance at the time of conception is popularly thought in many countries to be a cause of mental deficiency. Analyzing the last Swiss census, Bezzola pointed out that there are two maximal periods in which the mentally defective persons enumerated were conceived—the time of the vintage and the time of the Lenten carnival, occasions of great revelry. In the wine cantons the time of the vintage was the time of conception in a great majority of idiots. Ireland<sup>16</sup> examined the birth dates of mentally defective children born in certain villages in Scotland where there is much seasonal drunkenness to see if their conception dates bore a relation to such periods, but was unable to find any such evidence as that discovered by Bezzola. P. Nacke<sup>17</sup> gives it as his opinion that, while intoxication at the time of conception may result in mental deficiency in the offspring, such an event is extremely rare. This seems in accordance with the biological facts of conception. The extent of the popular belief that some delinquency on the part of the parents is responsible for mental deficiency in their children was impressed upon me while questioning the parents of mentally defective immigrants at Ellis Island. I had an opportunity to ask hundreds of such parents, representing nearly all the European races, what they considered to be the real cause of the mental deficiency of their children and, while many of them gave all kinds of infantile accidents and very few of them, as might be expected, suggested hereditary influence, a considerable number said shamefacedly that they thought it was due to intoxication at the time of conception, to early sexual faults or to failure to obey the Hebrew injunctions regarding intercourse after marriage.

Experiments such as those of Kraepelin<sup>18</sup> in memory tests, type-writing and typesetting indicate that even very moderate drinking no-

ticeably impairs mental efficiency. These are effects of alcohol which cannot be ignored in mental hygiene. See page 489.

**Preventive Measures.**—The prevention of the alcoholic psychoses and of those mental diseases in which alcohol is a contributory etiological factor consists in the control of alcoholism and the promotion of temperance. These matters are not within the scope of a chapter on mental hygiene. Like the prevention of syphilis, the control of alcoholism is a great social question. The medical man can help best by contributing information as to the ravages of these two enemies of the race and by using his personal and professional influence to aid all rational movements for reform. If alcohol is not to be denied to all, it would seem desirable to create some special safeguards for the neuropathic component of the population for whom it involves the gravest dangers. It is the duty of the physician to urge total abstinence for life upon such people.

At the Boston Psychopathic Hospital, Dr. E. E. Southard formed a club, membership in which was restricted to those who had recovered from delirium tremens or an alcoholic psychosis in that institution. Such associations—for mutual help and encouragement—of those to whom successful abstinence is the only means of preserving mental health or even life itself have been found elsewhere to be valuable aids.

The findings of Pollock that the psychoses come, as a rule, late in the course of chronic intemperance and often after repeated attacks of delirium tremens should give renewed impetus to all movements to reclaim the intemperate. The establishment of state and municipal colonies for the treatment of alcoholism will yield a rich return in the prevention of the alcoholic psychoses. Anyone interested in this movement should study the plans of the New York City Board of Inebriety and the management of the Farm Colony which that Board has established. Such movements as the "Big Brothers" are efficient forces in this work and much can be said in favor of their aid by public funds, in view of the valuable public service which they perform.

While groups of people, including those especially predisposed to alcoholism, can be protected to a certain extent by various movements for regulation of the liquor traffic, individual prophylaxis must depend chiefly if not wholly upon voluntary abstinence. Recent progress in the study of mental mechanisms has provided new knowledge of great value in understanding the sources from which the alcoholic craving really springs and, in not a few cases, in devising plans for prevention or successful treatment. Careful personal studies of many inebriates show quite clearly that inebriety usually represents a flight from reality very similar to that seen in the psychoses and neuroses (page 423). Determining by *psycho-analysis* and other methods of psychiatric investigation the nature of the difficult situation from which the individual seeks

to fly frequently discloses means of prevention as well as of cure. When it is impossible to modify the main factors which have given rise to conflicts in mental life, much may be done by securing a more constructive solution of the problem than that afforded by recourse to alcohol. Music, art, and literature present avenues of escape from difficult or intolerable situations in real life. Wounded self-esteem can be restored by the satisfaction which comes from labor for the welfare of others and the craving for alcohol as a means of forgetting or transforming actuality can often be directed into safe and even highly constructive activities. Such forms of compensation simply suggest that useful work in the prevention or control of inebriety can be accomplished by attempting to rehabilitate the individual by using psychological resources. It must be insisted upon, however, that this is an undertaking which cannot be carried on with groups. It is applicable to individuals and then only after careful personal analysis in each case. Our hope of controlling or treating inebriety more successfully depends, therefore, upon concentration upon *the individual inebriate*.

The Eighteenth Amendment to the Constitution of the United States represents the most sweeping effort yet made by any nation to control intemperance and alcoholism. Until the legislation framed to give effect to this amendment has been fully enforced it is impossible to make any statistical comparison of the prevalence of alcoholic psychoses before and after prohibition. Incidentally, this legislation constitutes an immense practical experiment in psychopathology and its effects upon the individual inebriate may, when any large number is actually required to abstain from alcohol, furnish valuable material and enable us to determine what some of the essential personal factors in alcoholism have been.

## OTHER EXOGENOUS POISONS

Morphinism and other drug addictions are responsible for less than 1 per cent. of first admissions to hospitals for the insane in this country. Fewer such patients are admitted in New York and Massachusetts now than were several years ago. This gratifying fact is due, in part at least, to stricter enforcement of the laws regulating the sale of narcotics and particularly to the food and drug laws which have rendered it a little more difficult to dispense habit-forming drugs in patent medicines. It is well within our power to eliminate this cause of mental disease by wise legislation and its rigid enforcement. See page 486.

A very small proportion of admissions is caused by occupational poisonings. This small proportion can be still further reduced by increasing attention to measures safeguarding workmen in dangerous trades.

## ENDOGENOUS POISONS

The endogenous poisons which are formed in the course of various organic diseases are responsible for not a few cases of mental disease. Their prevention is the work of general hygiene.

The relation of mental diseases to disturbances of the organs with internal secretions is a field for study which as yet is almost unexplored, but which may yield many opportunities for applying preventive measures.

Pellagra is responsible for thousands of cases of mental disease in the localities in which it is prevalent. The high hopes for the control of this disease which have been raised by the discoveries of Goldberger<sup>19</sup> make it practically certain that pellagra may now be properly counted a preventable cause of mental disease. The studies of Lorenz<sup>20</sup> in which it was shown that the pellagrous psychoses are undoubtedly toxic is an instance of the aid which psychiatry can often lend other branches of medicine in the new and useful alliance between the psychiatrist and the sanitarian. The non-infectious origin of pellagra was strongly indicated by Lorenz's findings and thus assistance was given toward clearing the way for the discoveries of Goldberger.

## SYPHILIS

**Psychoses.**—Among the infections, syphilis deserves separate consideration as a cause of mental diseases because it is the essential cause of general paresis, a psychosis responsible for over 14 per cent. of all male first admissions to hospitals for the insane. In one very large hospital, which receives its patients exclusively from New York City, one in four of the male patients admitted has general paresis. The prevalence of this disease is about three times as great among men as among women. Although general paresis is uniformly fatal, the number of deaths reported from this cause does not give an adequate idea of its frequency, for death in this disease usually results from some late complication, such as bronchopneumonia, or from some cerebral accident such as hemorrhage, which are direct results of general paresis itself. Although 830 paretics died in the New York State hospitals in the year ending June 30, 1919, only 742, or 89 per cent., of these deaths were reported as due to general paresis. If the same ratio existed in those dying outside institutions we know that not less than 1,000 patients with

<sup>19</sup> See page 686.

<sup>20</sup> Lorenz, William F.: "Mental Manifestations of Pellagra." *Public Health Reports*, February 4, 1916.

general paresis died in the State of New York during that year. However, deaths from this cause are much more likely to be reported as due to complicating disorders outside institutions than in them, where the mental condition naturally attracts the most attention. The mental symptoms of general paresis are so very often subordinate to the physical changes that admission to an institution for the insane is not necessary in all cases and still more frequently the existence of the disease is overlooked altogether. It is apparent, therefore, that general paresis is a cause of many more deaths than are attributed to it. Known cases cause more deaths in New York State than typhoid fever. The deaths from general paresis are very largely grouped in the two decades from 40 to 60, and in this age-period *one in thirty* of the deaths among men and *one in sixty-nine* of those among women are from this disease. The course of general paresis is usually from two to five years and the average hospital residence 1.2 years. It attacks people who have, to all appearances, recovered from syphilis and most frequently in the fourth decade of life when their usefulness to their families and to the community is greatest.

The relation of syphilis to general paresis has long been suspected, and even before the discovery by Moore and Noguchi of the *Treponema pallida* in the cerebral substance the belief was general among psychiatrists that all cases were due to this cause. Other undetermined factors apparently contribute to general paresis but syphilis is the *essential* cause; without syphilis there could be no general paresis. It is very desirable to know what proportion of cases of syphilis result in general paresis, but, until recently, no satisfactory studies had been undertaken to determine this, and, on account of the long interval between infection with syphilis and the development of symptoms of general paresis, it seemed impossible to find a group of population in which such studies could be made. Mattauschek and Pilez have reported the results of a careful examination of the histories of 4,134 officers of the Austrian Army who had contracted syphilis during the period 1880-1890. They ascertained that 4.67 per cent. of these officers developed general paresis.<sup>20a</sup>

It is a fact that general paresis is a much more frequent nervous form of syphilis than locomotor ataxia. The course of the latter disease is from six to eight times as long as that of general paresis and the number of persons living at one time with either disease is about the same.

A relatively small proportion of other psychoses are directly due to syphilis. Mental deterioration is associated with gummata of the brain and mental changes accompany local syphilitic meningitis. About one per cent. of all men admitted to hospitals for the insane and about half this proportion of women suffer from such form of cerebral syphilis.

<sup>20a</sup> *Berliner klinische Wochenschrift*, Feb. 19, 1912.

It is impossible to estimate the part played by syphilis in the causation of other mental diseases, but it is not to be disregarded. The train of pathological processes commencing with arterial changes and culminating later in organic changes in the brain with their accompanying mental disease is not infrequently started by infection with syphilis.

**Mental Deficiency.**—Syphilis has been thought to be an infrequent cause of mental deficiency. Tredgold says that only 2.5 per cent. of his cases presented undoubted marks of syphilis, while Fletcher Beach found syphilis in only 1.17 per cent. of 2,380 mentally defective persons examined in London. These percentages were ascertained before the general use of the Wassermann test. An examination of 400 patients in the asylums of the Metropolitan Asylum Board in London in 1913 by Gordon <sup>21</sup> showed positive reactions in 31.8 per cent. of cases with evidence of gross brain disease and in 11.9 per cent. of cases without such evidences. In this country Atwood <sup>22</sup> found positive reactions in 15 per cent. of all cases and Haines <sup>23</sup> found, in an examination of 365 children in reform schools in Ohio, no larger percentage among the mentally defective than among the normal children. Twenty per cent. of all cases examined gave a positive Wassermann reaction. It appears very probable that the percentages of mental deficiency attributed to syphilis represent only the prevalence of syphilis among the group of the population from which the mentally defective enter American institutions. The neuropathology of mental deficiency rarely suggests syphilis—either hereditary or acquired—and it seems likely that this is not a relatively important cause of mental deficiency. Tredgold believes that the existence or absence of neuropathic heredity determines whether or not hereditary syphilis will result in mental deficiency. The findings in not a few cases of so-called “syphilitic mental deficiency” show quite clearly that juvenile general paresis was the true condition present.

**Preventive Measures.**—The prevention of general paresis and other mental diseases which depend directly upon syphilis can be accomplished only by preventing well persons from contracting syphilis and by the early and effective treatment of syphilitics so that this late and fatal manifestation may be averted. There are enough cases of juvenile general paresis to make this danger an additional reason for inducing persons with syphilis to abstain from marriage. The prevention of syphilis is considered elsewhere (Section I, Chapter I). It is a rather surprising fact that many of those actively engaged in the campaign against venereal disease are quite unaware of the prevalence of general paresis or that it depends upon previous infection with syphilis. The

psychiatrist has nothing to add except the impressive statistics showing the great prevalence of this terrible result of syphilis and the earnest recommendation that opportunities for the early and thorough treatment of syphilis should be greatly increased. In the larger question of the control of prostitution, which is interwoven with that of venereal prophylaxis, the information being gleaned by psychiatric study of the springs of human conduct may some day give information which will enable mankind to understand prostitution better and deal with its causes more rationally.

Increased provision for the mentally defective will aid in limiting prostitution, for it has been shown that the feeble-minded form a prolific source for the recruiting of prostitutes. When the relation of syphilis to the causation of mental deficiency becomes better defined it may be shown that *provision for the mentally defective will decrease the prevalence of syphilis, and the control of syphilis will decrease in some measure the amount of mental deficiency.*

## OTHER INFECTIONS

**Psychoses.**—Other infectious diseases, notably typhoid fever, influenza, malarial fever, erysipelas, and septicemia (particularly from uterine infection), furnish a small number of cases of mental disease. From 1 to 2 per cent. of all first admissions are mental disease belonging to the "infective-exhaustive" group, in which elevation of temperature, exhaustion, and poisoning of the nervous centers by bacterial toxins act as direct causes. The proportion of women in psychoses in this group is about twice that of men, the difference being due to the number of puerperal cases. In other psychoses, acute infections often play a very important if secondary part, apparently "liberating" an attack or adding just enough stress to make the onset of the psychosis possible. Alcohol and the infections exert an influence together sometimes which neither cause can exert alone. It has been stated that tuberculosis is the cause of a definite psychosis, but there seems to be no evidence upon which to base this belief. Exhaustion psychoses occur in this disease as in typhoid fever.

**Mental Deficiency.**—The growing realization of the importance of heredity as a cause of mental deficiency has rather obscured other factors, but damage to the brain seems responsible for a considerable number of cases of mental deficiency in families where there is no evidence of neuropathic heredity or mental deficiency. Where cerebral hemorrhage occurs in the course of an infectious disease in infancy or early childhood mental deficiency may be one of the results and there is excellent evidence—both clinical and pathological—that bacterial toxins may permanently injure the brain cells or prevent their development. After cerebrospinal meningitis mental deficiency may result from gross damage to the brain

or from interference with development. Local meningitis from middle-ear disease following scarlet fever or measles may also cause mental deficiency. Serious impairment of the special senses as a result of damage to the cranial nerves may cause mental deficiency through deprivation. The large number of cases which have been attributed to the infections of childhood upon insufficient evidence while really due to unmistakable heredity has led to an undue skepticism regarding the influence of causes acting after birth. Goddard casts doubt upon the existence of such cases, except those resulting from cerebrospinal meningitis, by raising the question as to why such diseases as measles and whooping-cough result in mental deficiency in some cases and not in others. Even in those cases in which a cerebral hemorrhage has occurred during a paroxysm of whooping-cough, he asks, "Why does this child's blood vessel burst when others do not?" and answers his question by saying that it can only be because there is "a constitutional weakness of the vascular system which allows of a rupture here and not in other instances." It would be nearly as unreasonable to assert that heredity determines whether a typhoid fever patient has an intestinal perforation or does not or whether another has a lymphangitis or not. The fact is that any organ of the child can be affected in its integrity or its development by the infectious diseases through which he passes, and yet we are asked to believe that one of the most delicate of them all can be permanently injured only if heredity has already laid a foundation of predisposition. It is, of course, very desirable to know the mental condition of children *before* the occurrence of these accidental causes of mental deficiency in order that errors in diagnosis may be avoided.

**Preventive Measures.**—The prevention of the mental diseases and defects dependent upon infections consists in the prevention of the infectious diseases. The prevention of the infectious diseases is the task of preventive medicine and is considered in the first part of this work. More careful methods of treating febrile diseases and especially appreciation of the full significance of delirium will, among other beneficial effects, lessen by a small but appreciable number the cases of mental disease and mental defect which follow upon injury to the brain in such affections. Those individuals who respond very easily to delirium should receive most careful attention. Hydrotherapeutic measures will probably tend to prevent cerebral edema and changes in the brain cells.

## HEAD INJURIES

**Psychoses.**—A very small number of patients admitted to hospitals for the insane suffer from psychoses due directly to traumatism to the brain. Nearly all such cases are men. Injury to the brain often seems

to have a marked effect in precipitating psychoses in alcoholics and sometimes in other psychoses dependent primarily upon other causes. Street accidents and accidents from unprotected machinery are responsible for many head injuries, but by far the greater number, especially in alcoholics, are due to the too vigorous and indiscriminate use of policemen's clubs. The efficient regulation of traffic and the "safety first" movement are apparently diminishing the number of traumatic cases quite rapidly, but it is possible also that better methods of psychiatric study are assigning some of the cases previously thought to be traumatic to other more appropriate clinical groups.

**Mental Deficiency.**—Injury to the brain or cerebral hemorrhage occurring during birth may be looked upon as a cause of mental deficiency which is, to a certain extent, preventable. It is not quite as easy to determine whether or not brain injuries during infancy and early childhood are the essential cause of mental deficiency unless retardation or cessation in the mental development of the child is very apparent after the injury, for extensive damage, with definite focal signs, is often unaccompanied by mental defect and a history of head injury of one sort or another is almost always given by relatives in cases which are clearly hereditary. Nevertheless, there are not a few instances in which it seems beyond doubt that mental deficiency is caused by head injuries during infancy and early childhood.

**Preventive Measures.**—The frequency of traumatic psychoses is hardly great enough to warrant suggesting specific measures of prevention, but the "safety first" movement will prove useful here as well as in other unsuspected directions. The fairly numerous cases of brain injury due to the use of policemen's clubs might be lessened if police officials were given an idea of the thinness of the human skull and were shown a few persons with traumatic psychoses in our hospitals for the insane.

Injuries to the brain at birth depend in some part at least upon careless obstetric work and the long labors which the ignorant management of childbirth by midwives entails.

## MENTAL CAUSES

**Conflicts.**—Important recent additions to our knowledge concerning the psychology of mental diseases have brought about radical changes of opinion as to the part played by mental causes. The statistical tables of hospital reports have always listed as etiological factors "grief," "worry," "death of a relative," "fear," "remorse," "fright," and "disappointment in love." Large numbers of cases have been attributed to such causes as these without any knowledge as to the manner in which they operated.

It has been pointed out that they really represent little more than a catalogue of the untoward circumstances which, to a greater or less degree, shadow the life of every individual and that the proportion of persons who develop mental disease in consequence must be extremely small. This difficulty has been disposed of by the assumption that if only a few of those who are exposed to such adversities develop mental disease, an inherited neuropathic predisposition must determine this unfortunate outcome. Recent studies, however, especially those which have followed the enormously important discoveries of Sigmund Freud, have shown that the significance of such factors can be estimated only by understanding the part which they play in the mental lives of the individuals affected. Many factors which have been listed as causes of mental disease are now known to be merely striking circumstances attending the progress of psychoses or surface indications of deep-seated conflicts in personal life.

**Adaptation.**—The psychoses and the neuroses are often clearly seen to be attempts at adaptation—disastrous to be sure in most instances, but sometimes the only attempt possible under the circumstances. They represent, in many cases, flights into the unreal from intolerable situations in the life of the individual. Biologically, these results may not always be the most unsatisfactory solution, for they often prolong life. The psychosis is not infrequently an alternative to suicide. As society estimates success, however, they are failures in adaptation. It would be difficult, even if this entire chapter were available for the purpose, to describe the operation of mental mechanisms which lead in the one case to such a result and in others to a compensatory set of reactions which maintain the mental health and efficiency of the individual. One person deals with an intolerable situation by taking refuge in silence, inaccessibility and refusal to eat and, in consequence, goes to a hospital for the insane, while another devotes himself to altruistic work which not only increases his self-esteem and heals the hurts of an unkind fate, but at the same time benefits his fellow-men. The explanation of such differences in reactions to events would lead us deeply into analysis of the personality and the psychology of mental diseases. It is necessary, however, in order that some preventive principles may be presented, to outline in a very general way the conception of mental conflict which underlies the newer attitude toward the mental causes of mental disease.

**Adjustments.**—In order to gain an idea of the place which mental conflicts occupy in the life of the individual it is necessary to look upon existence as a continuous series of adjustments—some simple and some highly difficult and complex—between fundamental instinctive demands, on the one hand, and the requirements of society on the other. In the young infant, the care given by others makes these adjustments un-

necessary. If this care is not forthcoming the individual perishes, as there exists no mechanism by which adjustments can be made. In the child, the adjustments required are few and relatively easy, but as life unfolds they increase in number and complexity. The capacity for making these adjustments (upon which successful living depends) varies greatly in different individuals, partly as a result of differences in the inherent capacity for adjustment and partly as a result of failure to establish, through experience and education, the kind of mental mechanisms most likely to aid in making satisfactory adjustments. The first factor is beyond our present control in the individual—heredity has already determined it—the second, we are coming to believe, may be greatly modified by directing attention to education and experience.

**Behavior.**—These never-ending conflicts between the requirements of reality and the demands of instincts determine behavior—both individual and social. The sex instinct is involved most frequently and most profoundly in these conflicts. According to Freud, it is directly or indirectly involved in all. It is probably more within the bounds of moderation to consider these conflicts as involving any of the fundamental instincts, the sex instinct most often. It can readily be seen that the necessity for continuous adjustments between the powerful and unalterable urgings of the instincts and the constantly changing requirements of daily life presents innumerable opportunities for mishaps or for the establishment of habitual reactions which are undesirable. Few individuals achieve conspicuous success or conspicuous failure in this great struggle which makes up the most of mental life.

**Conflicts and Adjustment in Civil Life.**—A great deal of conflict is averted through the intervention of customs which society, quite unaware of their real purpose, has established to direct effort at adjustment along paths of little resistance. Traditions and codes which have long presented opportunities for unsuccessful conflict are constantly in process of modification. On the other hand, however, new developments in social life bring about new and complex situations. There seems to be evidence that the requirements of advancing civilization make, upon the whole, greater demands upon the capacity for adjustment than do those of more primitive social states. As Bernard Hart has pointed out,<sup>24</sup> very many social conventions might well be modified so as to provide alternatives to the ruthless decision that all individuals who cannot live within the narrow limits assigned by conventional and purely arbitrary standards of conduct must be segregated from society or even prohibited from reproducing their kind.

<sup>24</sup>Hart, Bernard: "The Psychology of Insanity," Cambridge, 1914.

## EXPERIENCE OF THE WORLD WAR

It is not easy to form an approximate idea of the number of persons who suffer from types of abnormal mental reactions other than those which have been mentioned. Before the war every internist and most surgeons knew that the psychoneuroses are responsible for an enormous amount of sickness and semi-invalidism in all civilized countries under such names as "neurasthenia," "hysteria," "nervous breakdown," "nervous prostration," etc. The psychoneuroses knew no distinctions of age, sex or social condition. Complicating other diseases they were known to be responsible for the unnecessary continuance of disability, the intensification of suffering and for a great deal of economic loss. In the World War, however, the psychoneuroses assumed striking proportions and the attention of physicians, who had previously ignored them or considered them relatively unimportant disorders affecting chiefly persons in fashionable life, was directed very strongly to the scientific consideration of these diseases.

**"Shell Shock" and Its Lessons.**—When the battered British divisions emerged from the fierce fighting in Belgium, stories came with them of new and scarcely credible effects of modern explosives. Men who had been exposed to shell fire but who bore no visible wounds were paralyzed, mute, dumb, or afflicted with strange jerkings and twitchings of muscles. Others seemed literally almost frozen into postures of attack, defense or fear. Others were confused or delirious, had lost their memories or were without control of their emotions. Such cases were not seen in really large numbers but nearly every unit had one, and the presence of more remarkable cases in other units was quickly spread by word of mouth and usually lost little in the telling. Some of the mental symptoms noticed were so similar to those seen in grave forms of mental disease that it was not long before even medical officers began to say that men had "lost their minds" as the result of concussion from high explosives. From all the armies—allied and enemy—came the same stories and a little later there appeared in hospitals at the base the same kinds of patients.

At the very outset a few physicians serving with troops and in the military hospitals noted the resemblance which these new disorders bore to the hysteria of civil life but even these observers were loath to believe that, appearing in men who might have been concussed by explosions or exposed to other as yet unknown effects of the new artillery, the weird symptoms seen might not represent a new form of disease or at least a striking modification of the psychoneuroses of civil life. British soldiers invented the terse, expressive term "shell shock" to designate all these conditions and in the shortest time imaginable it had come into

general use in the army not only among the officers and men of the line but among doctors and nurses as well. In civil life one heard it on every side. Two years later strenuous efforts were made, on account of the inestimable damage to morale that its indiscriminate use had wrought, to restrict this term to a certain class of cases, but so deeply imbedded was it in speech and thought that all these efforts failed.

In general, "shell shock" was thought to be the result of some unexplained physical phenomenon connected with the explosion of shells, bombs or mines. The French medical officers, who were generally familiar with the work of their own great students of functional nervous disease,—Charcot, Marie, Dubois, Janet and Babinski,—were perhaps better acquainted than their British colleagues with the neuroses as seen in civil life and were the first to adapt their management of these disorders in war to this conception of their real nature. They were also the first to separate cases in which concussion seemed actually to play an important part from those in which the situation giving rise to the disability seemed to be wholly emotional.

With the publication of reports of many individual cases, a long-continued controversy as to the nature of "shell shock" arose. The observations of a distinguished neuropathologist on the anatomical changes found in the brain and spinal cord of several cases in which men had been killed without visible injury by the explosion of shells or by being buried by parapets were accepted as evidence that in all or the greater number of "shell shock" cases minute injuries to the central nervous system would be found if examination could be made. Various theories were advanced to account for the types of damage discovered in cases coming to autopsy. Decompression after the high atmospheric concentration brought about by the explosions was said to cause the liberation of bubbles of gas in the blood stream. Inhalation of drift gases from the explosive while the soldier was lying unconscious was another method by which it was thought the central nervous system was frequently damaged.

Soon, however, evidence commenced to accumulate showing that, whatever organic basis there might be for "shell shock," there were many cases in which the causative factors were chiefly or wholly psychological. Men in training camps in England and France, especially those about to embark or entrain for active sectors, exhibited exactly the same symptoms as those reported in men who had become incapacitated under shell fire. Thousands of observations upon the wounded showed that very few had any psychoneurotic symptoms whatever, even when there was gross damage to the brain and spinal cord. A disproportionate rate among officers was difficult to explain on the grounds of injury. All sorts of extraordinary recoveries, such as would have been quite impossible if the extensive symptoms present had been the result of permanent

organic damage, commenced to be reported and psychological methods of treatment were found to be much more efficacious than any others. A comparison of the personal make-up and heredity of men who had "shell shock" with those of wounded men taken for control showed that among the former there was a heavy preponderance of men with a personal or family history of psychoneurotic make-up. The extreme rarity of neuroses among prisoners, even in large groups taken in the fiercest fighting, was pointed out. More and more, the resemblance of the war neuroses to those of civil life became apparent, especially when the vivid setting of the battlefield was replaced by that of the training camp in the histories of patients studied. Slowly the conception of "shell shock" as wholly in some cases and partly in most others a psychological disorder came into vogue among physicians. Laymen became dubious regarding certain phases of the affection but, in general, remained pretty firmly convinced of the validity of the first popular conception of "shell shock" as a new and unheard effect of the use of high explosives in modern warfare.

With this change in professional opinion (which was by no means universal) there came about new methods of treatment and certain changes in administrative management. The propriety of authorizing men with "shell shock" to wear wound stripes was questioned and an attempt made to regulate it so that only those who had actually been concussed in battle could acquire this badge of honor. The practical difficulties in the way of the enforcement of such regulations are, of course, obvious. The suspicion of malingering, which had existed in the minds of some at the very beginning, commenced to be expressed more frequently and the question was raised in Parliament several times as to the possibility of severe punishment being wrongly inflicted upon victims of these disorders by those who held this view. Against the spread of a rather less charitable attitude toward the "shell shockers" there was brought to bear the intense public sympathy that always went out toward men in such a pitiable condition and, up to the end of the war, there was little real change in the popular or official attitude toward soldiers with war neuroses.

Important modifications in treatment, however, reflected the medical change of opinion. Men who had strongly advocated a psychological approach to the treatment found it possible to secure influential supporters and in practically all the special hospitals for war neurosis cases in England, efforts were made to use psychotherapy in one form or another and to rely upon electricity, massage, passive exercise and other means directed toward the elimination of symptoms only as an adjuvant to analysis of the situation and reëducation of will.

The alarming accumulation of uncured cases in the hospitals led to the adoption of the policy of not sending any recovered cases back

to the front line duty. Those who saw the great dangers to morale that were involved in this plan warned the government that this measure would greatly increase the incidence of functional nervous diseases. Popular opinion, even among discharged wounded soldiers, supported it, however, and those who were attempting to cure the disease had forced into their hands a measure which promoted symptomatic recovery but constituted a new enemy to the morale of the individual.

Toward the beginning of 1917 some well trained psychiatrists and neurologists who were serving with troops had an opportunity to treat suitable cases in advanced sanitary formations. They had astonishing results. In their hands symptoms which had always proved most intractable in hospitals at the base were found to be readily removable. The whole course of the disease seemed in many instances to be within the power of these physicians to influence, and it was found relatively easy to prevent the fixation of psychoneurotic symptoms in exhausted soldiers and those who had undergone the severest emotional experiences if efforts could be commenced within a few hours from their onset. Some of the medical officers who had this experience attributed their success to the specific methods of treatment that they had used—such as hypnosis—but others saw that an important discovery in medico-military therapeutics had been made. About the same time the French, who from the first had dealt with these disorders from a psychological approach, put their theories fully into practice and established in each army area an army neurological hospital to which patients could be admitted from the trenches within a few hours and (of even more importance) from which they could be returned directly to duty as soon as their symptoms had disappeared.

It is necessary to go into this bit of medico-military history to this extent to draw a picture of the situation with regard to the management of the war neuroses in the armies of our allies up to and at the time of our own participation in the war. The methods of dealing with the psychoneuroses in war are quite important, for the lessons which a little later will be drawn from the war neuroses are in reality lessons from their management and not from the diseases themselves.

The prevalence of the neuroses during the full tide of war will indicate the practical importance of those disorders to a nation thrown back upon its uttermost resources in manpower. By July, 1917, 20 per cent. of all discharges from the British Army for disability had been for "shell shock" and allied conditions. When we remember that the proportion for wounds of all kinds was only 47 per cent. we can see how important, in a purely military sense, the withdrawal from active duty of this number of unwounded men must have been at a time when every effort was being made to comb out the last fit man and to

find some place of military usefulness for those who were only partially fit.

The immense number of persons with psychoneuroses who were studied in military hospitals during the war afforded striking opportunities for testing the soundness of such observations on the nature of the psychoses and psychoneuroses as have been given above. Out of this vast experiment have developed many new points of view, but the essential soundness of the modern conception of the part played by conflict in mental life has been demonstrated in an unexpectedly dramatic way. Whatever differences of opinion may exist, it seems fair to state that the opinion expressed by Dr. Sidney I. Schwab,<sup>25</sup> that the war neuroses are protective or defensive elaborations of the primary instinct of self-preservation in the face of destructive incidents of war, is accepted not only as sound in theory but as capable of having built upon it a structure of practical treatment, management and prophylaxis. With the observations of the English and French to guide us, our own army was able to put into effect a definite mechanism for the prophylaxis of psychoneuroses in the field. This was carried out through assigning to each tactical division a competent neuropsychiatrist. In the beginning many difficulties arose, some of them quite inseparable from the military situations, but in the St. Mihiel and Argonne-Meuse offensives a system of diagnosis, prevention and early treatment was put into effect with striking results. This consisted of the assignment of division, corps and army neuropsychiatrists, the concentration of small reserve groups of neuropsychiatrists at the advanced neurological hospitals, the careful examination and vigorous treatment of psychoneurotic patients in field sanitary units, more prolonged treatment in army units and the utilization of the special hospital in the Zone of the Advance. Of 100 men received at the "trriages" or sorting field hospitals, 65 were returned directly to their units for duty, in spite of a pressure for room in these divisional sanitary units occasioned by the enormous number of casualties. Of the 35 received at the army neurological hospitals, 20 were returned directly to their divisions for duty, and only 15 evacuated to the rear for treatment in a special hospital in the Zone of the Advance. This hospital (Base Hospital 117), in its entire work, had only 35 per cent. of its patients reclassified for non-combatant duty, and only 6 per cent. returned to the United States to be discharged from the military service for disability. Therefore, of 100 patients with psychoneurosis who came to the attention of the divisional neuropsychiatrists, only five were permanently invalided for non-combatant duty and only one returned to the United States. The

<sup>25</sup> Schwab, Sidney I. (formerly Major, M. C., U. S. A., Medical Director, Base Hospital 117, A. E. F.): "The War Neuroses as Physiologic Conservations." *Arch. of Neurology and Psychiatry*, May, 1919, V, 1, p. 579.

methods of treatment employed from the most advanced stations to the special base hospitals were, of course, individual and varied, but in all instances their foundation was the psychological conception of the nature of the psychoneuroses outlined in the preceding pages.

**Preventive Measures.**—There are special groups of the population in special need of assistance in making the adjustments to their environment upon which successful living depends. The idiot, like the young infant, is incapable of making even the simplest adjustments to the world about him and would perish if others did not make for him the adaptations which he cannot make for himself. Defectives of higher grade can make relatively simple adjustments and in an environment carefully arranged with reference to the extent of their adjusting capacity happy and useful living is possible. As Dr. C. Macfie Campbell has pointed out,<sup>26</sup> "the contented and industrious worker in an institution for the feeble-minded may have exactly the same constitution as his brother who is in jail for repeated criminal acts." It is not with the mentally defective, however, that this phase of mental hygiene chiefly concerns itself. Adjustments cannot be made by somebody else for one who is not mentally defective; they must be made by the individual and all that others can do is so to train and direct his activities that he will develop good mental reactions and so to aid him in selecting his environment that he will live upon the level which, *for him*, offers the best opportunities for efficient and happy existence. The practical application of these broad principles obviously depends upon the recognition of the capacities and limitations of the individual. As the reactions which determine success or failure in life are very largely established in childhood, it is to the child that preventive measures must chiefly be applied.

The enormous increase of interest in the mental life of childhood is leading to the recognition at a much earlier period than formerly of those factors which endanger mental health. Education must be fundamentally altered to fit the needs of subnormal children and those with special difficulties of adaptation. So numerous and so disastrous are the results of failure to make the modifications in teaching which these children require that the whole educational system might well be examined with reference to their special needs. Constant and increasing efforts should be made to determine the individual requirements of school children and the attention of the best educators should be given to devising means for furnishing such children with an equipment which will fit the *individual child* to live successfully, the *average child* being, for the moment, forgotten. Special classes exist now only for mentally defective children. They should be provided *for all kinds of atypical*

<sup>26</sup> Campbell, C. Macfie: "Educational Methods and Fundamental Causes of Dependency." *Mental Hygiene*, Vol. I, No. 1, p. 235. April, 1917.

*children*, intellectual defect representing only one and not perhaps the most important cause of imperfect mental adjustment.

Of the utmost importance, in laying the foundations in childhood for mental reactions which in later life may prevent psychoses, is the cultivation of a *frank emotional attitude*. Personal difficulties should never be dissembled but always faced in their reality. Children do not feel the same emotions as adults and the efforts of parents and teachers to make them feel or "act as if they felt" sympathy or sorrow or remorse, when they do not, simply plants the seeds for unreal emotional attitudes in later years. Recourse to the unreal is the habit which it is mental hygiene's great task to prevent. It is much better to have a child do something to relieve suffering than to induce him to act as if he felt an emotion which in reality he does not. Thus the objectivity of life will be intensified and this is perhaps the chief object of mental hygiene. Lyman Wells has said (what all psychiatrists know) <sup>27</sup> that self-love and self-consciousness constitute the great fountainhead of mental maladaptations. No other measures will more surely prevent their growth than the frank facing of actuality in childhood when mistakes can be acknowledged without loss of self-respect and rectified without difficulty. It is especially important that a frank emotional attitude toward sex should be established. The movement for instruction in sex hygiene has for its chief objects the control of venereal disease and the prevention of sexual immorality. If this movement grows upon a rational and strong foundation, these benefits will be far outweighed by its effect upon the general attitude toward sexual difficulties.

Preventive measures in this field of mental hygiene embrace a wide range of activities. All of them could hardly be enumerated here but the more fundamental ones may with advantage be summed up, even at the risk of being didactic, in these injunctions: determine the inherent capacity of each individual to make adjustments to his environment; realize that the causes of most maladjustments in later life arise in the early years of childhood; aid each individual to find the level at which he can live most successfully; cultivate a frank emotional attitude, especially in matters relating to sex; deal with actualities and so do not evade difficulties or transform them into a false situation; cultivate an objective view of life, enjoying to the full art, literature, music, and other desirable means of escaping into the world of unreality, but at the same time realizing their real nature; distribute interest throughout a wide range of activities, reserving an important place for those which do not contribute directly to self-gratification but which benefit others.

It is of the utmost importance in this field of mental hygiene to remember that individuals in need of assistance in making difficult ad-

<sup>27</sup> Wells, Lyman F.: "Mental Adaptation." *Mental Hygiene*, Vol. I, p. 60, Jan., 1917.

justments are rarely able to understand the situation or take the steps needed to bring about successful adjustments without the help of others and that those who give such help must possess psychiatric knowledge. This emphasizes the importance of mental clinics where such advice and guidance can be obtained. Every university should have a department of mental hygiene in charge of a well-qualified psychiatrist whose chief duty should be to help students to understand and deal with their personal problems. Every city school system should have such a department and should maintain school clinics in charge of competent psychiatrists for the examination and treatment of all children experiencing special difficulties. If these recommendations seem radical and expensive, it is only necessary to consider the enormous loss through mental diseases and other maladjustments which depend upon the causes that we have been considering and then remember that this is the one group of mental affections in which, at the present time, practically no efforts are being made for prevention.

Unless the experience in managing the psychoneuroses in war is to become simply an interesting and striking piece of medico-military history, it must be applied in civil life. The psychiatrist stationed at the "triage," examining closely into the nature of breaks in individual morale, should be regarded as the precursor of the school psychiatrist to whom are referred all children who have special difficulties in adaptation. The neurological hospitals just behind the line, in which the actual stress was occurring, must be followed by the establishment of school clinics and psychopathic hospitals where individuals wavering under the stress of adaptation to the economic, social and personal situations of modern life may have skilled advice and treatment. Base Hospital 117, a psychiatric hospital, which was never concerned with issues of insanity, must have its counterpart in hospitals for the study and treatment of the more severe types of psychoneuroses by psychotherapy, physiotherapy and every other aid known to modern psychopathology.

## ECONOMIC FACTORS

Unemployment, overwork, congestion of population, child labor, and the hundred economic causes which increase the stress of living for the poor are often contributing factors in the production of mental diseases. Weaknesses in constitutional make-up—defects in the armor of personality—are disclosed under the stress of such conditions, but might have remained undiscovered under happier circumstances. All that can be said of the prevention of such causes is that everything which makes for the betterment of those upon whom the stress of living falls heaviest will save many from mental disease. If the operation of these powerful

causes cannot be prevented, those who are most likely to be harmed might, perhaps, be shielded a little if the special danger which they face were more generally known.

### IMMIGRATION

No consideration of the preventable causes of mental diseases in this country would be complete without reference to this important element in our national life. It is a question peculiar to the United States. During the last 95 years 32,027,424 immigrants have come to this country.<sup>28</sup> This vast migration has no parallel in history. In some states the increment to the population from immigration every year exceeds that from births. Under such conditions movements such as those directed against alcohol, heredity, or the economic causes of insanity are feeble in their immediate effects compared with a thorough sifting of applicants for admission while they are still at our threshold. We have the absolutely unquestioned right to require any reasonable tests which can be proposed, and yet the present immigration law results in the mental examination of the smaller portion of the million immigrants who seek admission each year. There is no provision whatever requiring immigrants to present certificates from responsible authorities at home, testifying to their freedom from mental disease. These great numbers of immigrants, 30 per cent. of the adults illiterate and less than 20 per cent. with any trade, are, without adequate mental examination or selection, projected into our most congested centers of population, to bear, during their first years in America, as severe stress as any group of population can be called upon to endure. One result is that they are found in larger numbers in our hospitals for the insane than their ratio to the whole population warrants. Hundreds have to be returned during the first year for mental disease due to causes which existed before their arrival. In the succeeding years the proportion rises and in the next generation and the one succeeding it we shall doubtless reap the harvest for which our present policy is sowing the seed. It can be earnestly asserted, after long study of this question, that no measures for the control of mental diseases and mental deficiency which have yet been suggested can prove so efficacious as artificial selection of additions to our population on the vast scale which an adequate mental examination of immigrants would permit. This is a measure of practical eugenics which can be applied successfully now and one in which we shall not have to wait a generation to note the effect. As Professor R. DeC. Ward has said, "It is merely a question whether we or foreign steamship agents shall select the parents of future generations of Americans." The provisions of the federal immigration law which deal with the exclusion of insane immigrants are in need of

<sup>28</sup> January 1, 1820, to June 30, 1915.

thorough and immediate revision and the enforcement of the law should receive the attention which its importance deserves.

We have been far too careless of the welfare of recently landed immigrants. There seems to be a general impression that, however unsanitary their surroundings or however heavy may be the burdens placed upon them, immigrants are in some way fitted for such hardships, either by nature or through previous experiences in their homes. Of course, this assumption is without justification and it is time that the social, economic, physical, and moral welfare of these newcomers be given the earnest attention of the federal and state governments and of societies and individuals. By so doing something may be done to lessen the disproportionate prevalence of mental disease in this large group of our population.

### AGENCIES AVAILABLE FOR THE APPLICATION OF PREVENTIVE MEDICINE

It is possible to mention only very briefly some of the agencies which can be utilized in the application of preventive measures.

**Hospitals for Mental Disease.**—A very large proportion of the persons with mental disease in any state will be found under treatment in public institutions. This is not the case with other diseases, sufferers from which are widely scattered, in their homes, at work, and in hospitals. This fact makes the hospital for the insane seem the logical place in which preventive measures should originate. As Adolf Meyer<sup>29</sup> has said: "A modern hospital must get together the material with which to reconstruct the patient's life. It must be in touch with the patient's home. . . ."

No agency for practical work in prevention and the diffusion of knowledge regarding mental diseases and the mental factors in other diseases can compare with the university psychiatric clinic. Situated in large centers of population, such clinics are centers for research, treatment, prophylaxis, and education. Their influence is felt in every department of the universities in which they are located and their social contacts are so extensive that no person who has to deal with mental problems, whether he be parent, teacher, magistrate or social worker, goes from them empty-handed. Largely on account of the popularization of neuropsychiatry among physicians and laymen as a result of the war, the demand for university psychiatric clinics is rapidly spreading in this country. It seems now quite certain that within ten years' time every graduate of a Class A medical school will be taught mental medi-

<sup>29</sup> Meyer, Adolf: "Organizing the Community for the Protection of Its Mental Life." *The Survey*, September 18, 1915, p. 557.

cine in such a center. This is a development which might have been expected to follow the increase of interest in all the lesser mental disorders which existed in the military service, but the fact that such a clinic can establish and maintain the closest contact with the social, educational and the economic life of the community in which it is placed is due chiefly to the work of the late Dr. E. E. Southard at the Boston Psychopathic Hospital. No consideration of the psychopathic hospital as an agent in mental hygiene is complete without testimony to the vision, energy and resourcefulness which enabled Dr. Southard to show the community that it needed the psychopathic hospital and to show the psychopathologist that he was needed in the community.

**Public Health Authorities.**—No better illustration of the fact that mental hygiene has become one of the recognized activities of health authorities can be found than the proposal to create a division of mental hygiene in the United States Public Health Service. A bill to provide such a division is now before Congress. Several state departments of health are circulating information regarding mental hygiene in their work of educational publicity. Following the example of the Department of Preventive Medicine and Hygiene of Harvard Medical School, courses in mental hygiene are now given in the public health departments of many universities. Special courses for teachers, nurses and other groups are being established throughout the country. A new development of much importance is the special training of medical and social workers in psychiatric social work. This was undertaken at Smith College during the war in order to prepare young women for work with returning disabled soldiers. It has been so rapidly extended that there are now no less than a dozen schools for social work in the United States giving special courses for psychiatric social workers.

**Educational Authorities.**—Under the direction of state boards of administration and encouraged by national and state societies for mental hygiene, much can be done toward placing the education of psychopathic and defective children upon a better basis. These children are now chiefly interesting to school authorities, for they constitute a special class and should receive separate instruction, both for their own good and the good of normal children whose progress is retarded on account of the excessive amount of time teachers must give defective children. They should have a far greater interest for the state than this, for every child is a possible patient in a hospital for the insane. It would seem desirable for the state to provide very liberally for the study of these children and for their training. To this end, school clinics and special classes in the public schools should be fostered by the state educational authorities and even subsidized by the state when desirable.

**National and Local Societies for Mental Hygiene.**—There is a very clearly defined field of effort for national and local societies in the work

of prevention of mental diseases. As has been indicated, the care of the insane is, far more than that of any other class of the sick, in official hands. There is besides a great deal in the methods of commitment and provisions for care pending commitment which is regarded wholly as an official matter. For this reason there is decided need for agencies which can bridge the gap between the usual environment of the patient and the public institution which is to assume his care. A certain part of the social service work which has so useful a place in the care of the insane, particularly in the period following discharge from institutions, should be done by workers under the direction of institutional authorities, but there is also a very great deal which can be done better by societies co-operating with institutional authorities but not officially connected with them. In New York State the "Committee on Mental Hygiene" of the State Charities Aid Association has a local committee in each hospital district. Although after-care and efforts to improve the kind of care afforded the insane in that critical period while commitment is pending constitute the chief work of such committees, there is often opportunity for effective work in prevention, especially in popular education regarding preventable causes. In Alabama, California, Connecticut, District of Columbia, Illinois, Louisiana, Maryland, Massachusetts, North Carolina, Ohio, Pennsylvania, Rhode Island, Iowa, Virginia, Kansas, Georgia, Mississippi and Oregon, there are societies for mental hygiene doing most useful work.

There is a National Committee for Mental Hygiene, coördinating and, in a measure, directing these local activities. This committee has commenced studies of existing provisions for the care of the insane and mentally defective in all the states, methods of commitment and care pending commitment, the influence of preventable causes, etc. With a carefully prepared plan of work, accurate information is being obtained upon these matters, and, as fast as the facts in the possession of the committee justify it, active work is undertaken for amelioration or prevention. It is believed that a great deal can be done, especially in the direction of standardizing work for the care of the insane and the prevention of insanity, and in coördinating the efforts of the hospitals, state boards of administration and some of those organizations which (sometimes unawares) are attacking preventable causes of mental diseases and mental deficiency from different angles. The National Committee aims to stimulate interest on the part of the federal, state and local authorities charged with health work and the care of the insane and mentally defective and to sustain interest when otherwise it might flag. Standards established in states where advanced ideas prevail are being made known in states where there is indifference or lack of progress. A central "clearing house" for the collection and distribution of accurate information regarding the care and prevention of mental diseases and mental

deficiency is provided. Earlier treatment and the transfer of care pending commitment from the policeman to the doctor—the most urgent needs of the insane—are important aims of this organization. The lamentable failure to provide instruction in mental diseases in the medical schools is being shown and the means are being suggested for remedying this defect in medical education. It is a fact that the number of beds in the institutions for the insane in this country is almost equal to the numbers of beds in all the general hospitals of the United States. The insane are, therefore, the most numerous class of the sick receiving public care. As such, they are entitled to a much larger share of the interest of every practitioner than they receive. Progress in every branch of preventive medicine depends chiefly upon the leadership of physicians. In this particular field there is need of much wider interest on the part of the medical profession than exists today. One of the functions of the National Committee for Mental Hygiene is to broaden and increase this kind of interest.

### CONCLUSION

The attempt has been made to outline some of the preventable causes of mental diseases and mental deficiency and to indicate, very broadly, possible preventive measures. It seems essential that, notwithstanding the complexity of some of the questions involved, the prevention of mental diseases and mental deficiency should be considered in the general advance which is being made against diseases, for it is very closely related to all the other fields of preventive medicine. Recent advances in the field of psychiatry have given grounds for encouragement, for, if the outlook in some directions is not bright the accuracy with which the part played by certain causes is being defined promises much. The fact that it has been definitely determined that there are certain *essential* causes of mental disease and mental deficiency, and that some of these essential causes are entirely controllable, makes it imperative that preventive measures should be energetically promoted. At the same time the great advantages in the promotion of mental efficiency which may result from better understanding of the nature and importance of mental conflicts and of the means by which more successful adaptations may be made should lead to developments in the constructive phases of mental hygiene which, in the end, may prove the greatest service to mankind of this branch of hygiene.

### SECTION III

## PUBLIC HEALTH MEASURES AND METHODS

### CHAPTER I

#### SOME GENERAL CONSIDERATIONS

**Sources of Infection.**—There are two great sources of the communicable diseases of man, viz.: (1) man himself, and (2) the lower animals. Most of the communicable diseases of man, especially those which occur in epidemic form, are peculiar to man. This is the case with typhoid fever, cholera, leprosy, malaria, yellow fever, syphilis, mumps, measles, scarlet fever, typhus fever, infantile paralysis, small-pox, chickenpox, relapsing fever, dengue, and even tuberculosis in large part. It is quite true that some of these infections may be communicated to the lower animals under experimental conditions, but they do not, as a rule, occur in them under natural conditions. In other words, most of the communicable diseases from which man suffers are specific for man; the degree of specificity varying slightly with the different infections.

It is, therefore, plain that man is the great source and reservoir of human infections. Man is man's greatest foe in this regard. The fact that most of the communicable diseases must be fought in the light of an infection spread from man to man is one of the most important advances in preventive medicine. This new thought has crystallized out of a mass of work in the sanitary sciences during the past decade, especially from researches upon tuberculosis, typhoid fever, cerebrospinal meningitis, and other communicable diseases. Formerly, sanitarians regarded the environment as the main source of infection. We now know that water, soil, air, and food may be the vehicles by which the viruses of the communicable diseases are sometimes transferred—that is, they are media of conveyance rather than sources of infection. Most of the microorganisms causing the communicable diseases of man are frail and soon die in our environment, as in the air, soil, or water. Most of them are obligate pathogens and cannot, or do not, grow and multiply under the adverse conditions of our environment.

From the lower animals, particularly the domesticated animals, man contracts a number of infections. Thus we contract rabies and echino-

coccus cysts from the dog; plague from the rat; glanders from the horse; trichinosis from hogs; anthrax from cattle; Malta fever from goats; foot-and-mouth disease from cattle; tuberculosis, in part, from cattle; tapeworms and other animal parasites from the meat of fish, fowl, and mammals. Various skin parasites are also contracted from the lower animals, as ringworm from cats, fleas from dogs, etc. The number of these diseases<sup>1</sup> and the extent of their ravages are notably less than those contracted from man himself.

The association between man and the domestic animals is intimate, and the contact with rats, mice, and vermin is much closer and more frequent than we suspect. While man contracts several infections from such relations, animals on the other hand contract a few diseases from man, such as trichinosis, *Taenia solium*, *Taenia saginata*, and cowpox.

The fact that most infections are spread rather directly from man to man brings in the forces of sociology to aid those of preventive medicine. The task of preventive medicine is rendered much more difficult from the fact that most infections depend upon the control of man himself. We ruthlessly wage war against insects or against infected food or water. In other words, we can arbitrarily control our environment to a very great extent, but the control of man himself requires the consent of the governed. Thus, it is easier to stamp out yellow fever than to control typhoid fever. It is easier to suppress malaria than syphilis, rabies than influenza, trichinosis than measles. Cattle appear to be mutely thankful when protected by inoculation against blackleg or anthrax, but man rebels against one of the best of all specifics—vaccination against smallpox. The fact that man is the chief source and reservoir of most of his own infections adds greatly to the scope and difficulties of public health work and often makes the prevention of disease dependent upon social and economic changes. In this sense preventive medicine is a very important factor in sociology.

**Modes of Transference.**—The viruses of the communicable diseases may take various routes of transference from man to man or from animal to man. These routes are spoken of as the modes of infection, the modes of transference, or sometimes as the vehicles of infection. Formerly they were spoken of as the "channels of infection," but now we restrict that term to the special channels by which the infection enters the body. Thus, the channel of infection in tuberculosis may be the respiratory tract, the digestive system, or the skin; whereas the mode of infection is from tuberculous sputum, either by direct contact or through the air, as in droplet infection, or through milk or some other vehicle.

The modes of transference may be grouped, for convenience, under

<sup>1</sup> A list of the diseases of animals associated with human diseases is given by Davis in *Science*, Sept. 8, 1916, N. S. XLIV, 1132, p. 339.

three general heads: (1) direct, (2) indirect, and (3) through an intermediate host. In the great majority of cases the virus is transferred more or less directly by what is now known as contact infection. In many instances the virus is transferred indirectly through water, food, soil, air, etc. In a large group of diseases the transfer is through an intermediate host which furnishes the growing list of insect-borne diseases.

The transfer is usually quite direct from one person to the next. The agents of infection, as a rule, do not travel far. The danger diminishes inversely as "the cube of the distance." However, viruses may be spread broadcast in water and milk; they are also transported great distances in the host along the routes of trade and travel, by cases and carriers.

*Contact Infection.*—"Contact infection" is a convenient term intended to include a group of circumstances in which infection is spread more or less directly from person to person. Contact infection assumes a quick transfer of fresh infective material. Actual contact between the two individuals is not necessary, but the conveyance is, nevertheless, pretty close in time and space. Contact infection alone may be responsible for epidemic outbreaks, even in the case of such a disease as typhoid fever.

The diseases in which contact infection plays a dominant rôle are those in which the virus leaves the body in the discharges from the mouth and nose, as tuberculosis, diphtheria, scarlet fever, measles, influenza, common colds, cerebrospinal meningitis, whooping-cough, mumps, etc. Contact infection also plays a large rôle in diseases in which the virus leaves the body in the fecal and urinary discharges, as in typhoid, cholera, dysentery, and other intestinal infections.

Contact plays a dominant part in such diseases as syphilis, gonorrhea, skin and other infections having open sores on the surface of the body.

In contact infection the virus may be transferred from man to man directly by actual contact, as in kissing, or more indirectly upon soiled hands, contaminated towels, or infected cups, spoons, toys, remnants of food, and other objects which have recently been mouthed or handled by the infected person. Droplet infection is also included under the convenient term "contact." As a matter of fact, the ways by which the infection may be transferred, and still be considered contact infection, are numerous and varied. In every instance, however, the transfer is brought about by pretty close association with the infected person.

*Indirect Infection.*—A large group of diseases are conveyed indirectly from person to person through water, food, soil, and fomites. Diseases may be conveyed great distances by means of food or water; they are never conveyed long distances through the air. In the large majority of the diseases contracted by indirect infection the virus is

taken into the system through the mouth and discharged from the body in the feces. The best examples of this class are typhoid fever, cholera, and dysentery. The relation of soil, food, water, air, and our environment to disease is discussed separately.

The insect-borne diseases form a large and important group, which are fully discussed in Chapter IV, page 259.

**Carriers.**—By the term “carrier” we understand a person who is harboring a pathogenic microorganism, but who, nevertheless, shows no signs or symptoms of the disease. Thus a person may have diphtheria bacilli in the nose and throat, but, nevertheless, be in good health. The same is true with the pneumococcus, the meningococcus, streptococcus, and many other microorganisms. Persons may have typhoid bacilli, cholera vibrio, or hookworms in their intestinal tract without showing manifestations of these parasites. Furthermore, persons may have plasmodia in their blood or spleen without having clinical malaria, and so on through a long list of infections.

Persons who harbor pathogenic bacilli without showing symptoms are known as “bacillus carriers,” those who harbor protozoa are known as “protozoön carriers,” etc. Carriers may be acute or temporary, chronic or permanent, convalescent, passive or active, intermittent, intestinal, oral, urinary, etc. These terms are defined on page 540.

The demonstration that many persons are carriers has thrown a new light upon the control of the communicable diseases. With the new facts has come a realization of added difficulties. Carriers can only be detected by painstaking laboratory examinations. When discovered their control is as difficult as it is important. We cannot lightly imprison persons in good health, even though they are a menace to others, especially in the case of breadwinners. In some infections there are so many carriers that it would require military rule to carry out such a plan. Fortunately in most cases absolute quarantine is not necessary. Sanitary isolation is sufficient. Thus the danger from a typhoid carrier may be neutralized if the person exercises scrupulous and intelligent cleanliness, and is not allowed to handle food intended for others. Such a person might well engage as carpenter, banker, seamstress, etc., without endangering his fellowmen.

The fact that carriers exist in a large number of diseases makes their suppression one of great practical difficulty. The cure of carriers is one of the pressing problems in preventive medicine. One hopeful feature of the carrier situation is that their number may be diminished by isolating and diminishing the cases of the corresponding disease. Thus, the number of typhoid carriers falls off sharply as a result of any successful measure directed only against the clinical cases. The facts concerning carriers have been discussed separately under each disease in which they occur.

**Missed Cases.**—By missed cases we understand mild and atypical instances of disease which are not recognized clinically. Almost all diseases vary greatly in severity. Thus we have walking typhoid and ambulant plague. Whooping-cough, scarlet fever, yellow fever, influenza, and most other infections may be so mild that they escape notice. Even the patient himself may not know he is sick. These mild cases go to school, ride in street cars, attend theaters, continue at their usual work in crowded factories and other places, handle our food, eat at restaurants, and thus spread infection. It is now well known that missed cases are a prolific source of spreading the infection of many of the communicable diseases; they form an important factor in preventive medicine.

**Channels of Infection.**—There are numerous channels by which infection may enter the body. These are usually grouped under three headings: (1) the respiratory tract, (2) the digestive tract, and (3) through the skin. Perhaps 90 per cent. of all infections are taken into the body through the mouth. They reach the mouth in water, food, fingers, dust, and upon the innumerable objects that are sometimes placed in the mouth. The fact that the great majority of infections enter by way of the mouth gives scientific direction to personal hygiene. Sanitary habits demand that the hands should be washed after defecation and always before eating, and fingers should be kept away from the mouth and nose, and that no unnecessary objects should be mouthed. All food and drink should be clean and thoroughly cooked. These simple precautions alone would prevent many a case of infection.

Viruses taken in by the mouth and nose do not necessarily cause respiratory infections. Thus, the viruses of cerebrospinal fever and infantile paralysis enter the system by the mouth; so also with typhoid fever, dysentery, cholera and other intestinal infections.

**"Contagious" and "Infectious."**—These are popular terms which lack scientific precision. The words have been used in very diverse senses.

A *contagious* (*contingere*, to touch) disease is one that is readily communicable—in common parlance, "catching." Formerly a contagious disease was considered as one which is caught from another by contact, by the breath, or by effluvia. A contagious disease implies direct or personal contact. If contagious diseases are limited to those contracted by direct contact or touch, as the etymology of the word signifies, only syphilis and diseases similarly contracted would be contagious. As a matter of fact, smallpox, measles, and influenza are types of contagious diseases, as the term is now usually understood.

An *infectious* (*inficere*, to put in, dip in, or mix in) disease is usually considered as one not conveyed directly and obviously, as in the case of contagion, but indirectly through some hidden influence or medium. In the days when specific febrile diseases were regarded as caused by mias-

mata and noxious effluvia, the terms "infectious" and "miasmatic" diseases were more or less synonymous. Typhoid fever was often taken as a type of an infectious disease. Malaria was the type of a miasmatic disease.

These distinctions are entirely artificial, and serve no useful purpose. Most of the communicable diseases may be transmitted from the sick to the sound in several ways. Infectious diseases may be contagious, and contagious diseases are infectious. Dividing diseases into those which are contagious and those which are infectious entirely leaves out of consideration the important class of insect-borne diseases. The terms contagious and infectious have always lacked scientific precision and have been the source of some confusion. The word "communicable" is a much better term and should be given preference.

A *communicable* disease is one caused by a specific virus transferred in a great variety of ways. The term "communicable" ignores the mode of transference. There is a great difference in the degree of communicability; some diseases are readily communicable, others transmitted with difficulty. The evidences of communicability are not so obvious in chronic infections, such as tuberculosis, or in diseases with a long period of incubation, such as typhoid fever. The relationship between one case and the next is often far removed in time and space. If tuberculosis were an acute infection like diphtheria it would be popularly regarded as being just as contagious as that disease.

**Epidemic, Endemic, Pandemic, and Prosodemic.**—A disease is said to be *epidemic* (*epi*, on, upon, and *demos*, people) when it is common to or affecting a large number of persons in a community in a short time. A disease which spreads rapidly and attacks many people at the same time is usually said to be epidemic. An epidemic involves the conception of time, place and numbers.

A disease is said to be *endemic* (*en*, in, *demos*, people) when it is peculiar to a district or particular locality, or limited to a class of persons. An endemic disease is one which is constantly present to a greater or less degree in any place. An endemic disease smolders, whereas an epidemic bursts into flames. A *sporadic* (occurring singly) disease is one in which a few scattering cases occur now and then.

Endemic diseases are apt to flare up and become epidemic. Insect-borne diseases are the best examples of endemicity, as their prevalence is strictly limited by the geographic distribution of the intermediate host. Yellow fever has long been endemic in Havana, cholera in India, typhoid fever in Washington, and plague in Tibet.

These terms not only lack precision, but are variously conceived and differently defined. Thus typhoid fever was said to prevail in Boston, but a similar number of cases in Berlin would have been regarded as an epidemic. For the purposes of maritime quarantine a disease is con-

sidered epidemic if there is more than one focus of infection; that is, if several cases occur which have no apparent connection with each other. Strictly, therefore, according to this definition, two cases may constitute an official epidemic and the port would, therefore, be regarded as infected.

It is not feasible to state just how many cases of a disease constitute an epidemic. Ordinarily a few cases of a communicable disease in a village or small town is not regarded as an epidemic; however, five cases of typhoid fever in Podunk (population 1,000) is the equivalent of 5,000 cases in a city of 1,000,000. By the same token, one or two cases in a small village would proportionately constitute an epidemic of unknown magnitude in a metropolis.

"*Pandemic*" (*pan*, all, *demos*, people) is a term used to describe a disease which is more or less epidemic everywhere. Pandemics affect a large number of people in a large number of countries at the same time. Thus there have been four great pandemics of plague, when it spread to the four quarters of the globe. In 1889-90 and again in 1918-19 influenza was pandemic. It is not usual, although quite proper, to regard tuberculosis, syphilis and typhoid fever as pandemic.

Sedgwick proposes the term "*prosodemic*" (*proso*, through, *demos*, people) to take the place of the unsatisfactory word "endemic." Proso-demic suggests the creeping or smoldering of a disease which is being communicated from person to person through the community by various means, but especially by contact.

**Fomites** (from *fomes*, touch-wood or tinder) is defined as any substance capable of absorbing, retaining, or transporting infectious germs. Fomites usually refers to inanimate things, such as bedding, clothing, etc. The term was especially used in connection with yellow fever, in which the greatest variety of objects, such as a lock of hair, the false bottom of a trunk, coffee sacks, a mattress, and letters were said to be the fomites which touched off an epidemic. Woolen clothing or the doctor's beard are popular and supposedly dangerous examples of fomites.

The importance of inanimate objects as vectors of pathogenic micro-organisms is assuming a minor rôle in the minds of most sanitarians. Thus we no longer think of such objects as books, umbrellas, floors, walls, curtains, and furniture as likely to transmit the virus of disease. We know that most of the pathogenic bacteria soon die when exposed to dryness and other adverse conditions of environment. We now concentrate our efforts more upon handkerchiefs, towels, bed and body linen, drinking cups, remnants of food, toys, pencils, table-ware, and other objects that have recently been mouthed by the infected individual. Such fomites may readily transfer fresh, live and virulent virus from one person to the next.

## RELATIVE VALUES OF PUBLIC HEALTH WORK

It is evidently impossible to express with mathematical precision the relative importance of different public health procedures. Nevertheless, efficient administration requires a sense of proportion. The relative values of health activities vary with location, character of population, stage of civilization, etc. In many communities malaria, dysentery, hookworm disease, plague or yellow fever will need chief consideration. A well sewered city can appropriate money for lines of work which in less fortunate places must be devoted to the never ending task of privy sanitation.

Sanitation or municipal housecleaning logically comes first; this accomplished, hygiene must occupy most of the attention of the public health administrator. Disease prevention is important, but health conservation is fundamental; education is essential, but scientific research is basic. The ideal of preventive medicine is to build towards departments dealing with health rather than departments dealing with disease.

In what way should the appropriations for the health department be expended so as to save the most lives and prevent the most sickness? Chapin<sup>2</sup> answers this question in the following table:

RELATIVE VALUES OF HEALTH WORK				
Communicable Diseases	{	Medical Inspection.....	100	
		Nursing .....		
		Hospitalization .....	50	
		Immunization .....	50	
		Venereal diseases.....	20	
Tuberculosis.....	{	Nurses .....	60	
		Dispensaries .....	40	
		Hospitalization .....	40	
	School Inspection.....		80	
	Child Hygiene.....	{		80
Nurses .....			80	
Supervision of Midwives .....			10	
Infant Mortality.....				
Boarding houses.....			5	
Milk stations.....			5	
Consultations .....			20	
Sanitation.....	{	Prenatal clinics.....	10	
		Privy Sanitation.....	110	
		Housing .....	20	
		Plumbing .....	10	
		Nuisances .....	10	
Food.....	{	Fly and Mosquito control.....	10	
		Adulteration .....	0	
Milk.....	{	Sanitation .....	10	
		Adulteration .....	3	
		Sanitation .....	17	
		Care of sick poor.....	50	
		Laboratory .....	50	
		Education .....	80	
Vital Statistics .....	60			
			1000	

<sup>2</sup> J. A. M. A., July 14, 1917, p. 90, LXIX, 2.

The figures given in the schedule are intended to indicate the real health conserving value of certain common functions of municipal health departments. For many activities we have no measurement, but only guesses.

Schneider <sup>3</sup> calculates the relative values of the various public health activities, as follows:

CONTROL OF COMMUNICABLE DISEASES:	
Tuberculosis .....	12.1
Venereal diseases.....	6.6
All others.....	25.3
Infant hygiene.....	20.3
Privy and well sanitation.....	3.5
Milk control.....	2.7
Fly and mosquito suppression.....	2.4
Food sanitation.....	0.1
Inspection of school children.....	7.0
Vital Statistics.....	5.0
Education .....	5.0
Dispensary and clinics.....	5.0
Laboratory .....	5.0
Total .....	100.0

It is interesting to note that, in Schneider's opinion, the control of communicable diseases and infant hygiene work might profitably constitute two-thirds of the activities of the health department.

Brooks <sup>4</sup> of the New York State Department of Health uses the following score:

1. Communicable diseases:	
(a) Tuberculosis .....	60
(b) Other than tuberculosis .....	80
2. Laboratory facilities, local or State, fully utilized .....	90
3. School inspection .....	85
4. Infant and maternal welfare .....	90
5. Milk and food inspection .....	80
6. Water supply .....	90
7. Sewage, garbage and manure .....	80
8. Record keeping .....	90
9. Public health education .....	100
10. Appropriation .....	100
11. Enforcement of regulations regarding barber shops, common towels and eating and drinking utensils .....	20
12. Special work along new or unusual lines or especially efficient work or good results with old methods .....	35

<sup>3</sup> *Amer. Jour. P. H.*, VI, 9, Sept., 1916.

<sup>4</sup> *Health News, Monthly Bull.*, N. Y. State Dep't. Health, May, 1919.

Olson <sup>5</sup> proposes the following score card for measuring the efficiency of local health officers.

### SCORE CARD—FOR SCORING THE EFFICIENCY OF LOCAL HEALTH OFFICERS

#### 1. Activities

Character of Activity	Score in Points	
	Perfect	Allowed
1. Communicable diseases: Suppression and prevention.....	18	.....
2. Laboratory diagnosis: Collection and transmission of specimens for diagnosis and investigation. Distribution of antitoxins and serums.....	10	.....
3. Education of public: Exhibits, lectures, circulars, newspaper articles, etc.....	8	.....
4. Vital statistics.....	7	.....
5. Coördination of extraneous health agencies.....	6	.....
6. Concurrent disinfection.....	6	.....
7. Infant and maternal welfare work.....	6	.....
8. Public health nursing.....	5	.....
9. Control of water supplies.....	4	.....
10. Inspection and control of milk supplies and dairies.....	4	.....
11. Occupational disease: Prevention and control.....	4	.....
12. Medical inspection of school children and correction of defects.....	4	.....
13. Mental hygiene.....	3	.....
14. Control of such preventable diseases as heart and kidney diseases, etc.....	3	.....
15. Clerical work: Correspondence, records, and reports....	3	.....
16. Sewage disposal.....	3	.....
17. Attendance at conferences, board of health meetings, etc..	3	.....
18. Food and meat inspections and control of slaughter houses, butcher shops, and grocery stores.....	1	.....
19. Inspection of public buildings.....	1	.....
20. Terminal fumigation.....	$\frac{1}{2}$	.....
21. Investigation and abatement of nuisances.....	$\frac{1}{2}$	.....
Total .....	100	.....

#### 2. Equipment

Nature of Equipment	Score in Points	
	Perfect	Allowed
1. Telephone .....	20	.....
2. Transportation .....	17	.....
3. Clerk .....	12	.....
4. Office .....	10	.....
5. Report cards:		.....
a. From physicians.....	5	.....
b. To State board of health.....	5	.....
6. Quarantine placards.....	8	.....
7. Vaccine and antitoxins or facilities for obtaining same..	7	.....
8. Record books or filing cases.....	6	.....
9. Literature for self-education and reference.....	5	.....
10. Literature for distribution.....	4	.....
11. Fumigants or facilities for obtaining same.....	1	.....
Total .....	100	.....

<sup>5</sup> U. S. Public Health Rpts., Jan. 14, 1921, Vol. XXXVI, No. 23, p. 31.

**A Score for Health Activities.**—The New York State Department of Health has prepared an activities score for cities with a population of from 25,000 to 175,000 inhabitants. Of a possible 1,000 points for perfect, adequate public health nursing service counts 75; other follow-up social service 10; adequate dispensary or clinic service 70; hospital facilities for the communicable diseases 45; a day nursery 10; Little Mothers' League 10; good newspaper publicity regarding health matters 50; and a physician in charge of the infant welfare station 15. This gives a total of 285 points for activities in which the nurse is directly concerned. In general the score provides the following distribution of credit:

Communicable disease control:	
Tuberculosis, perfect score.....	60
Venereal diseases, perfect score.....	70
Other communicable diseases, perfect score.....	80
Adequate laboratory facilities and use of same.....	100
Infant and maternal welfare.....	90
Milk and food inspection.....	100
Water supply.....	100
Sewage, garbage and manure disposal.....	40
Record keeping.....	85
Public health education.....	120
An appropriation of at least 50 cents per capita for health protection..	100
Effective enforcement of regulations governing barber shops, common towels, drinking and eating utensils.....	20
Unusually meritorious public health work along either new or old lines	35
Total.....	1,000

**A Public Health Program.**—The principal elements in a comprehensive public health program, in ordered sequence, may be named as follows:

1. Eugenics, the principles of sound breeding and heredity. Immunity.
2. Maternity and the care, protection and encouragement of the function of motherhood.
3. Infant welfare and the reduction of infant mortality.
4. The health and development (physical, mental and moral) of the school child and adolescent.
5. Food and nutrition, the relation of diet to growth and health.
6. Personal hygiene. Mental hygiene.
7. Industrial hygiene, the health of the worker.
8. The prevention of the communicable diseases. Epidemiology.
9. The prevention of the non-communicable diseases.
10. Sanitation, or biologic cleanliness, including improved environment. Sanitary engineering. Disposal of wastes.

11. Vital statistics, the bookkeeping of humanity.

12. Education, the diffusion of knowledge among the people in all these matters.

13. Research to extend the boundaries of knowledge.

Successful public health administration should be organized so as to include constructive work under each of these headings. In a broad sense, it should also include improvements in education for medical, dental, veterinary, nursing and public health practice.

**Organization of Health Departments.**—The administration of a health department should include as much as possible of the above public health program. Ordinarily, health work falls under the following headings:

1. Executive and administrative.
2. Vital statistics.
3. Communicable diseases—epidemiology.
4. Infant welfare and child hygiene.
5. Food and drugs.
6. Sanitation.
7. Industrial hygiene.
8. Laboratories.
9. Education.

A health department should have a "commissioner of health" or "health officer" as executive head of all activities. The chief executive may have a "public health council" or "advisory board" to approve policies and regulations, but such boards should have no executive duties. In metropolitan cities and states, the health departments should have skilled and trained heads for each of the above mentioned departments. It is sometimes advisable to have special departments for some of the major public health problems, such as tuberculosis or venereal diseases; or malaria, hookworm, plague, etc., where such diseases prevail.

The smallest health department must contain all the elements essential to public health work, and should consist of at least one health officer, one public health nurse and one clerk, all full-time employees. The health officer for small communities must be epidemiologist, educator, dispensary and school physician, bacteriologist, inspector, executive, etc. He should be free to call upon expert advice when confronted with an unusual situation. Such specialists are provided by both the U. S. Public Health Service, by state departments of health, by universities and other organizations.

It is a great advantage for a number of small communities to pool their health interests and resources. This has worked well at Wellesley, Massachusetts, where five of the neighboring towns have entered into

a cooperative health organization. The plan has worked well and should be copied widely.

Each county may have its own health organization, and all progressive states are divided into sanitary districts presided over by a district health officer.

**Cost.**—The appropriation necessary to maintain a minimum health organization varies from 50 cents to \$1.00 per capita per annum. For a city of 10,000 population, 75 cents per capita would be sufficient to maintain a minimum organization as follows:<sup>a</sup>

One health officer .....	\$3,000
One public health nurse .....	1,200
One clerk .....	1,000
<hr/>	
Salaries .....	\$5,200
Maintenance .....	2,300
<hr/>	
Total .....	\$7,500
All full-time.	

In a city of 25,000 population, 75 cents would hardly cover the expense, as a city that size should have a small isolation hospital. The organization for a city of 25,000 follows:

One health officer .....	\$3,500
One epidemiologist .....	2,500
Three public health nurses—\$1,200....	3,600
One milk inspector .....	1,500
One sanitary inspector .....	1,200
One statistical clerk.....	1,200
One stenographer.....	1,000
<hr/>	
Salaries .....	\$14,500
Maintenance .....	4,250
<hr/>	
Total .....	\$18,750
All full-time.	

In this organization, the epidemiologist performs the duties of bacteriologist, and he divides the duties of school inspector and dispensary physician with the health officer.

No provision is made for the collection of garbage and other city wastes, street cleaning, etc. These activities quite properly belong to a separate department of the city government.

In some cities and states, the management of public hospitals, tuberculosis sanatoria and insane asylums are placed under the control of the health office. The organization of health departments varies in different parts of the country to meet special conditions and local traditions.

<sup>a</sup> Fox, C.: Minimum Standards of Organization for Municipal Health Departments. *J. A. M. A.*, Sept. 18, 1920, Vol. 75, No. 12, p. 790.

*THE MEDIAN ENDEMIC INDEX*

In epidemiological work, it is essential that the health officer have some system by which he may compare the incidence of disease in the past with that of the present. For this purpose, Dr. W. H. Brown, then Epidemiologist of the Massachusetts Department of Public Health, devised an endemic index card. The endemic index was determined by averaging the number of reported cases for five years, exclusive of epidemics, for the various municipalities of the state. This average was the endemic index. The personal factor, however, entered into this determination as it was necessary for the epidemiologist to decide what constituted an epidemic.

To obviate this difficulty, Hitchcock and Carey of the Massachusetts Department of Public Health devised a median endemic index. This median endemic index is a record of actual occurrence and takes into consideration all cases reported. The data is arranged in arithmetical sequence, and the median selected as the index. For example, the number of cases reported for the month of January for nine years was as follows:

Year	Diphtheria	Scarlet Fever
1910.....	912	943
1911.....	992	631
1912.....	519	583
1913.....	555	833
1914.....	846	1,584
1915.....	921	953
1916.....	840	948
1917.....	869	673
1918.....	950	609

By arranging these numbers in arithmetical sequence and picking the median for the index, the median indices for January are found to be:

Diphtheria—869.

Scarlet fever—833.

The monthly endemic indices for the various diseases are plotted on a graph, and beside it is placed a dial marked off in suitable spacing to show the daily increase. This is recorded by two clock hands, the hour hand pointing to the endemic index for the month and the minute hand progressing as cases accumulate.

An endemic index card is kept for each city or town in the state. This card is ruled off in six large spaces on each side for the months of the year. Each of these large spaces is in turn ruled off into smaller

spaces for the days of the months and the diseases reportable. The number of cases reported the previous year and the endemic indices for the various diseases are also recorded. As daily reports are received, they are tabulated in their proper place.

The median index chart used in conjunction with a spot map and daily index cards is a simple and effective device whereby the daily accumulation of reported disease may be watched and which will show at a glance any sudden or unusual increase.

## HEALTH CENTERS

*Health centers*<sup>7</sup> are local agencies where the health activities of a community are administered. This concentration increases efficiency and promotes economies. Health centers are needed in metropolitan cities as well as in country districts; their organization, however, will vary somewhat in large cities, in medium sized towns and rural situations. Health centers are "clearing houses" for all hygienic, sanitary, medical, dental, nursing and other public health activities. They also serve as convenient places for advice and information; they are useful for promoting public health education and they may contain attractive social features.

One of the faults with public health administration is that it is too remote and removed from the people and their problems. Public health centers correct this fault in an admirable way. It is proper for a health center to have facilities for prenatal work, maternity care, baby hygiene station, child welfare, tuberculosis clinic, venereal dispensary, dental service, nursing service, Red Cross activities, mental hygiene, distribution of serums, and vaccines, physical examinations, surgical emergencies, etc., etc. Health centers may also serve as the district office for federal, state and local health officials, as well as for private organizations. Charity and material relief should be kept separate from such centers.

Health centers are the next step in health community service. Their possibilities are boundless, but their successful operation requires co-operation and leadership. Thus far there are few types and no models.

## HOUSING

*Housing* has an intimate relation to health. Housing influences morbidity and mortality, but in a rather indirect way. It is difficult to separate the factors of crowding, personal habits, poverty, food and other hygienic and sanitary influences from the actual housing conditions. A house after all is only an instrument that may be abused, thus a good

<sup>7</sup> A symposium on the Health Center, *Am. Jour. of Public Health*, March, 1921, Vol. XI, No. 3, p. 212.

house may be crowded and unsanitary, while a poor house may be clean and fairly adequate. Good housing conditions facilitate an adequate supply of fresh air and sunshine, promote cleanliness and dryness, and favor sanitary isolation; good housing also encourages higher standards of living, and thus favors better personal hygiene and improved sanitation of the environment.

Housing conditions may be taken as a good index of the general sanitary condition and hygienic habits of the occupants. Strict laws concerning new construction should be rigidly enforced, especially with respect to safety, air space, openings for air and sunshine, water supply and disposal of wastes, cellars, toilets, kitchens, etc. Regulations concerning the number of occupants and the use of the house should be made a matter of supervision through official inspection.

There is a difference of opinion as to the function of a health officer in relation to housing. In my judgment, it comes under the purview of good health administration, although it is largely an economic and social problem. Most of the laws in the United States concerned with housing deal more with structural safety than with sanitary requirements.

The modern tendency is to leave the country for the city. About one-half of our population is urban. Cities are congested and crowded, and many live in cells unfit for human habitation. The best results in health cannot be obtained and maintained when so large a proportion of our inhabitants live such a parasitic life. Housing is an index of these conditions and tendencies, which favor the spread of all communicable infections. Further, such artificial and unnatural conditions of life make it difficult to maintain tone, vitality and efficiency.

Housing affects health, morals and progress both directly and indirectly. Dark rooms favor the spread of tuberculosis. Dingy houses make cleanliness difficult and give comfort to vermin. Indirectly, bad housing conditions may undermine resistance to disease, especially through poor lighting, bad ventilation, and improper heating. The present lack of housing facilities is a serious sanitary menace.

One of the most important factors in housing in relation to health is overcrowding. Strict regulations should be enforced by the health officer to prohibit the overuse of living and sleeping rooms. Careful sanitary supervision is necessary to insure an abundant supply of good water and an adequate system of disposal of wastes. The health officer should also take cognizance of nuisances often maintained both within and without houses. It is usually easier to prevent such nuisances than to abate them. The records of the health officer should show the cases of sickness occurring in each house, for much useful information is thus obtained.

The general types of dwelling concerned in urban housing problems are: (a) one-family dwellings, (b) two-family dwellings, and (c) tene-

ments. The detached one-family dwelling with space all around it is the ideal.

Good housing includes a consideration of construction, site, soil, dryness and drainage, water and wastes, lighting, heating and ventilation, size, arrangement and use of rooms, facilities for cleanliness, and also the environment of the structure. Each one of these topics is discussed in detail in other chapters. See index.

### *RURAL SANITATION*

The country is the weakest link in the sanitary chain. This is largely due to economic reasons, with the added handicaps of inadequate organization, great distances, and imperfect education. Most rural health departments are under-manned, poorly supported, and render inadequate service.

From the standpoint of the communicable diseases, our better cities are now much safer places to live in than country districts. Before the days of modern sanitation, the cities had about double the death rates of the country.

Infection flows from the country to the city in the water, milk and food supplies. It is carried back and forth in the persons of cases and carriers. Opportunities for contact infection are much more frequent among the rural population than is ordinarily conceived; disease transmitted by contact infection often spreads through sparsely settled country districts like wildfire.

Rural dwellings, schools and meeting houses are often unsanitary, crowded and dark. Sewage disposal is apt to be primitive and the control of insects, rats and vermin difficult and neglected. Heating, lighting and ventilation are often defective. There is plenty of sunshine in the fields, but often none in the houses. Further, it is rather difficult for each farmhouse to surround itself with the tidy environment equal to that of a city park. The best medical service has a tendency to desert country practice for city allurements.

The farmer's work is fatiguing, intensive and seasonal. It often requires undue exposure to wind and weather both summer and winter. The hours are long and the conditions of work and life not always conducive to health, longevity and efficiency.

Over fifty per cent. of our population is rural, but this half receives scant attention. Rural sanitation is expensive, but costs less than sickness, with its attendant inefficiency and block to progress caused by disease.

There should be a full-time health officer in charge of a county or a rural sanitary district, with a health center and staff to carry on the needed work. Hospital, transportation and nursing services should

be organized and provided in each sanitary district on an economic basis.

The method of controlling disease, disposing of wastes, improving housing and ventilation and the art of sanitary living both in country and city are discussed in detail under specific chapters throughout this book.

### **PUBLIC HEALTH EDUCATION**

Public health education is fundamental. It must be considered under two aspects: (1) Acquisition of knowledge and (2) Diffusion of knowledge.

The first involves researches in laboratories, studies at the bed-side and investigations in the field. The demonstrations of science underlie all sound health administration and are the only safe guide for health education. Special schools are needed to prepare for public health service; and better instruction in hygiene and sanitation is called for in medical schools.

In the diffusion of knowledge concerning health and the prevention of diseases, public health authorities should take a leading part. Many other agencies, however, assist in placing the facts plainly before the people. Health education should begin in the home where the developing child is taught the art of sanitary living. The schools should teach the structure and functions of the body, hygiene of the person and sanitation of his surroundings. This is the most important part of the curriculum from kindergarten to university.

The popular methods in health education are through newspapers, periodicals, pictures, bulletins, exhibits, lectures, movies and feature campaigns, such as "Health Week," "Baby Week," "Clean-Up Week," etc. The doctors are also looked to as guides and counselors in health matters. Hospitals, dispensaries, and health centers, as well as nurses, social service workers and others, are effective and helpful.

Coöperation and assistance in Health Education may be obtained from the U. S. Public Health Service, from state health departments and local health officers; from the Federal Child Bureau, as well as the U. S. Bureaus of Education, Census and Mines; also from the U. S. Department of Agriculture, The American Society for the Study and Prevention of Tuberculosis, The Red Cross, The Russell Sage Foundation, The International Health Board, The Metropolitan Life Insurance Company, The American Society for Control of Cancer, the American Safety Council, The National Child Welfare Committee and other agencies.

It is very important that the facts stated in popular propaganda should tell the truth. It is more important to be correct than to be clever. Half truths are often dangerous. Wrong teaching undermines con-

fidence in health authorities. It is a question whether the subject is dignified by the use of circus methods, or the antics of the clown.

## INFANT MORTALITY

"Infant mortality is the most sensitive index we possess of social welfare. If babies were well born and well cared for, their mortality would be negligible" (Newsholme).

Of every five babies born, one dies before it is able to walk and talk. The awakening of the world to the consciousness of the immense and needless sacrifice of infant life is recent. Most of it has come since about 1870, as the result of statistical studies showing how colossal has been this "slaughter of the innocents." The reasons for regarding infant mortality as a major public health problem are humanitarian, social and economic. Good results in lessening infant mortality depend entirely upon attacking the underlying causes with intelligence. This is one of the functions of every well organized health department. Rewardful results are purchasable.

Queen Anne had 18 or 19 children, none of whom were living at her death. Most of them died in infancy, and only one—the Duke of Gloucester—reached the age of 11 years. In those days, they "did not expect to raise them all." While conditions have greatly improved, infant mortality almost everywhere is still excessive. The best figures are from New Zealand. Our own figures are meager and imperfect. Comparisons may be misleading unless we are assured of the accuracy of birth and death returns and other factors.

Infant mortality means deaths under one year of age. The infant mortality rate is the ratio of deaths under one year to births during the same period; the births being the easiest method of determining the number in this age group. There are a number of inaccuracies in infant mortality rates, which are mostly too high, because of incomplete birth registration, while that of deaths is usually fairly reliable (page 1275).

*Stillbirths* are not included in infant mortality. Registrars, however, require all premature and all stillbirths to be recorded by a birth and a death certificate. For the purposes of vital statistics, *abortion* includes fetuses up to four months of pregnancy; *miscarriage*, between four and six months; *premature births*, from six months (the age of viability), to fetal maturity. If the child breathes at all, it must not be recorded as a stillbirth.

Infant mortality is greater in cities than in the country, not because of the better environment of country life and air, but because most of the important conditions which cause high infant mortality are concentrated in cities. Infant mortality rates are not determined by the

size of the city or the density of population, but by the hygiene, sanitation and character of the population; thus, we have the following infantile death rate from the United States Census of 1900:

New York State .....	159.8
New York City .....	189.4
Nashua, N. H. ....	261.0
Lowell, Mass. ....	275.5
Fall River, Mass. ....	304.7
Mobile, Ala. ....	344.5
Savannah, Ga. ....	387.5
Charleston, S. C. ....	419.5

Nashua, Lowell and Fall River are typical factory towns, but not large ones. A similar very high infantile death rate is seen in factory towns in England and elsewhere. This is due largely to the gainful employment of mothers in factories, and hence bottle-feeding and neglect of the babies. During the siege of Paris in 1871, while the general mortality doubled, the infant mortality fell 40 per cent.; opportunities for outside work were shut off and women were compelled to stay home; so nursed their babies.<sup>8</sup>

There is a marked contrast between the death rate of children of the poor and those of the rich. Infant mortality is a class disease. In this case, money may purchase health and even life itself. Thus, Clay estimates that in England in the aristocratic families the mortality of the first year is 10 per cent.; in the middle class, 21 per cent.; in the laboring class, 32 per cent. Acute gastro-intestinal diseases are chiefly responsible for this. Halle states that of 170 infantile deaths from gastro-intestinal diseases investigated in Graz in 1903 and 1904, there were 161 among the poor, 9 among the well-to-do, and none among the rich. Corresponding figures are obtained wherever this subject is studied.

A high infant mortality results in a sacrifice of the *unfortunate* as well as the *unfit*. Newton was a premature, posthumous baby, saved only by careful ministration. Poverty and ignorance are, therefore, underlying factors of great importance in this problem.

The mortality is especially high during the first few weeks of life. Ten per cent. of the deaths during the first year occur on the first day. Most of these (about 70 per cent.) are due to prematurity and injury at birth. From 25 to 40 per cent. of the total deaths during the first year occur during the first month of life. Some of these (about 10 per cent.) are due to diarrheal diseases, but most of them are due to prematurity, congenital debility and malformation.

<sup>8</sup> Brehmer: *Wochenschr. f. Saualingsfursorge*, 1907, 209.

Infant mortality constitutes from 20 to 25 per cent. of all deaths.

**The Causes of Infant Mortality.**—The death returns to the health officer usually cover only the last thing which happened to the child. The real causes which are back of this terminal disease do not appear on the records. Diarrhea, bronchitis, and pneumonia are often end conditions which would not have occurred or would not have been fatal without some other condition, as malnutrition, neglect, ignorance, or marasmus, which existed weeks or months before the final few days of acute illness which closed the scene.

The underlying factor of infant mortality is infancy itself—the period in which the flame flickers feeblest. Most infants die primarily from accidental and therefore preventable causes—the fundamental causes are the results of poverty, ignorance and neglect.

The chief specific causes that increase infant mortality are artificial feeding; hot weather; dirty, stale, and bacteria laden milk; bad feeding; illegitimacy; lack of prenatal care; gainful occupations of mothers; midwifery; poor housing; lack of cleanliness; alcoholism, syphilis and other diseases; imperfect hygiene and sanitation. The causes, then, are multiple and exceedingly complex, and include social and economic factors.

A study of 44,226 deaths under one year in the four largest American cities gives the following causes of infantile deaths:

	Per cent.	
Acute gastro-intestinal disease .....	28.0	} 72%
Prematurity, congenital debility and marasmus .....	25.5	
Acute respiratory diseases .....	18.5	
Acute infectious diseases .....	5.4	
Tuberculosis (all forms) .....	2.0	
Syphilis .....	1.2	
Malformations, injuries at birth and other conditions of the new-born .....	5.8	
Convulsions .....	3.4	
All others .....	10.2	

From the above analysis, it is at once evident that 72 per cent. of the total infant mortality is made up of the first three causes.

The relative importance of these causes varies with the age of the infant; thus, nearly 70 per cent. of deaths occurring on the first day of life are due to group 1 of the tabulation on the next page.

Sepsis in the new-born formerly carried off many babies. This has been largely reduced by aseptic methods in obstetrics. The toll is still large where these principles are not practiced. See Tetanus Neonatorum, page 99.

Vaccination has reduced deaths from smallpox, which used to be

a children's disease. Improvement in the control of other communicable infections has also helped reduce infant mortality.

Another tabulation of causes follows:

	Per cent.	
1. Prematurity, congenital defects, debility and accidents at birth .....	25	} 40 } 85
2. Diseases of nutrition .....	15	
3. Acute gastro-intestinal diseases .....	25	
4. Acute respiratory diseases .....	20	
5. Acute infectious diseases .....	3	
6. Tuberculosis .....	2	
7. Syphilis (direct effects) .....	1	
8. Unclassified .....	9	
	<hr/> 100	

*Gastro-intestinal Diseases.*—Gastro-intestinal diseases comprise the largest single factor almost everywhere; in fact, the curve of diarrheal diseases largely controls the curve of infant mortality. These diseases embrace acute gastritis, gastro-enteritis, diarrheas, dysentery, infectious diarrheas, and cholera infantum—often termed summer complaints.

There are three underlying causes of gastro-intestinal diseases of the first year: (1) atmospheric heat; (2) methods of feeding; (3) infection; all of which are favored by city residence.

The withering effects of heat, especially when combined with humidity, are well known. Indoor air in crowded tenement districts may be hot and humid, while the temperature and humidity at the observation stations of the weather bureau indicate pleasant weather.

There is the closest possible connection between the frequency and fatality of diarrheal diseases and methods of feeding. The chances are about one to ten against the bottle-fed baby. Eighty-five per cent. of all infant deaths are bottle-fed babies; 90 per cent. of infant deaths from diarrheal diseases are bottle-fed. The figures are sufficiently impressive to emphasize the importance of breast-feeding in prevention. This one measure alone would reduce infant mortality one-third.

Hope, of Liverpool, has shown that in 1,000 breast-fed infants under three months there were only 20 deaths from diarrheal diseases; when in 1,000 bottle-fed babies under three months there were 300 deaths. Of 1,000 fatal cases of diarrheal diseases investigated by the New York Health Department in 1908, only 90 has previously been entirely breast-fed. Newsholme gives almost identical figures for England; namely, 10 per cent. of deaths in breast-fed infants, and 90 per cent. in bottle-fed infants.

It is not artificial feeding, *per se*, as is shown by the relatively fewer deaths in the bottle-fed babies among the well-to-do. Secondary factors are bad milk, unsuitable foods, improper methods of feeding, lack of maternal care, bad surroundings, especially heat, humidity, lack of cleanliness and overcrowding, which favors the spread of infection; in short, imperfect hygiene and sanitation.

Breast-feeding requires but little experience and may be very successfully done even by those with a very low grade of intelligence and among the poor; but artificial feeding is not successful, unless carried on with much intelligence and experience and at the same time with a certain amount of money to secure reliable materials, especially pure milk.

The method of feeding is especially important in prematurity, congenital debility, marasmus and inanition; also at the first indications of gastro-intestinal disturbance in a previously healthy child.

Many of the diarrheal diseases of infants are true bacillary dysenteries, or infectious diarrheas of specific cause. They are transmitted in all the ways that typhoid fever and dysentery are transmitted. Sanitary isolation, the boiling of diapers and aseptic technic of food and clothing are essential to protect babies against these preventable infections.

*Bronchitis* and *pneumonia* are responsible for about 18 per cent. of the total infant mortality. Overcrowding favors the spread of these infections, and common colds, influenza, streptococcal and pneumococcal infections are very apt to cause severe bronchitis or bronchopneumonia in infants. These conditions are often terminal and not at all the true cause of the baby's death.

All forms of *tuberculosis* constitute about 2 per cent. of infantile deaths. This is doubtless an under-estimate because of the difficulty in recognizing this disease in infancy. The care of the baby is often left to the sick father or mother while the other members of the family are at their work. Tuberculosis does not usually manifest itself early, but the infection contracted in infancy may remain latent and later in life break out into the clinical disease. See page 175.

*Syphilis* accounts for about 1.2 per cent. of infantile deaths. These figures include only the direct effects of the spirochete. The prevention consists in prompt treatment of parents, etc. See page 85.

*Acute communicable diseases* account for only 5.4 per cent. of infantile deaths. Whooping-cough makes up about half, and measles and erysipelas most of the remainder, for the other diseases are relatively infrequent in the first year.

*Premature birth* or *feebleness* at birth too great to support an independent existence is responsible for many early deaths. Alcohol and syphilis are prime factors favoring these conditions. This group includes congenital debility, marasmus and inanition. It is in this group that

prenatal care and proper hospital provision for premature infants is especially helpful.

Prenatal care and especially a period of rest and good food before confinement will increase the weight, vigor and maturity of the baby.

**Prevention.**—The prevention of infant mortality consists in attacking the problem at its root, in concentrating upon the preventable causes, and focusing attention upon the mother. Attacking the problem at these points will give rewardful results. The preventable causes of infant mortality<sup>9</sup> may be grouped as follows:

1. Those but little influenced by treatment:

Malformations.

Extreme feebleness or prematurity (before the seventh month).

Certain accidents during birth.

2. Those capable of considerable reduction, chiefly through proper hygiene, sanitary isolation and medical treatment:

Tuberculosis. Syphilis.

Acute respiratory diseases.

Acute contagious diseases—Whooping-cough, measles, and diphtheria.

3. Those capable of a very great reduction through proper feeding and care:

Acute gastro-intestinal diseases.

Marasmus and inanition.

Prematurity, after seventh month.

Poverty and ignorance require social justice and education. Other means of prevention are: prenatal care, hospitals for premature infants, milk depots, educational clinics, public health nursing, encouragement of breast-feeding, competent and compulsory medical supervision of infancy, clean milk, pasteurization, escape from city heat, better housing, scattering of crowded tenements, cleanliness, better artificial feeding when necessary, sanitary isolation from dysentery and other intestinal diseases, also from influenza, common colds, pneumonia and other respiratory infections. Milk depots, little mothers' leagues, social service workers, public health nurses, and improvement in medical and obstetrical practice are part of the program. Foundlings and orphans should be raised in homes rather than in institutions.

<sup>9</sup> Much of this material is taken from the excellent articles by Dr. L. Emmett Holt on "Infant Mortality and Its Reduction, Especially in New York City," *Journal of the American Medical Association*, February 26, 1910; and "Infant Mortality Ancient and Modern," *Archives of Pediatrics*, XXX, 12, December, 1913. Both these publications contain selective bibliographies. Consult also the publications of the *American Association for the Study and Prevention of Infant Mortality*, the *Archives of Pediatrics*, etc.

## PUBLIC HEALTH NURSING

Public health nursing is one of the most important links in the chain of efficient public health administration. The duties of the public health nurse are vague and varied. They include instruction and social work as well as nursing; in fact, nursing may be a small part of the duties of a public health "nurse," and the term is therefore misleading. The office of the public health nurse is part of an organized community effort to prevent sickness, maintain efficiency, prolong life, relieve suffering and promote individual and public health. The nursing itself must be preventive as well as curative or palliative.

The public health nursing movement is recent but has grown steadily. The first district nursing association was established in Liverpool in 1859; the first in the United States was the Instructive District Nursing Association in Boston in 1886. The movement has now received recognition, is an established and important part of public health work, and is making rapid progress.

Specialists are required for certain problems, such as the venereal diseases, tuberculosis, infant and child welfare, school nursing; also mental hygiene, industrial nursing, medical social service, and dental hygiene. Each of these special fields requires special qualifications which can be had only through training and experience. In addition, all communities require public health nurses prepared for general service. A model plan of organization includes both the general nurse and specialists.

About one public health nurse is needed for each 3,000 population; in addition one tuberculosis nurse for each 20,000, and one school nurse for each 1,500 children. The public health nurse should be in close touch with the board of health and many other public and private agencies in the community. She should not furnish material relief.

## NUISANCES

A nuisance may be defined as "the use of one's property in such a way as to injure the rights of others, and to inflict damages." Popularly

a nuisance is an annoyance. Statutory definitions are usually more explicit and include nuisances not directly related to public health. A comprehensive statutory definition is: "Whatever is dangerous to human life, and whatever renders soil, air, water, or food impure or unwholesome, are declared to be nuisances, and every person, either owner, agent, or occupant, having aided in creating or contributing to the same, or who may suffer to continue or retain any of them shall be deemed guilty of a misdemeanor."<sup>10</sup>

The following are considered nuisances in different states and cities: Filth, such as garbage, ashes, and slops, either on private property or on public highways; cesspools, privy vaults, sink drains, dumps, and dirty yards; low, wet, and soggy lands; defective plumbing and draining; faulty cellars; overcrowding of tenements and lodging houses, or dwellings unfit for habitation; excavations; weeds; flowers with offensive odors; foul closets on railroad coaches; dirty street cars; use of salt on streets in snowy weather; disturbing noises; spitting in public places; keeping of horses and cattle in city limits; manure; hogs; hog-pens, stables and barns; fowls; dead animals; filthy shores; stagnant water and marshes; offensive businesses and trades; places where liquor is sold illegally; and offenses against decency. While some of these conditions may favor the spread of the communicable diseases, yet most nuisances are not serious health problems.

The phrase "source of filth or cause of sickness" used in the statutes of no less than fourteen states, is copied verbatim from a law enacted in Massachusetts in 1797. At that time miasmatic vapors and the inhalations from decomposing organic matter were believed to be the principal causes of the contagious diseases. The Supreme Court of Massachusetts, however, has ruled that "in order to amount to a nuisance it is not necessary that the corruption of the atmosphere should be such as to be dangerous to health; it is sufficient that the effluvia are offensive to the senses and render habitations uncomfortable."

By far the greatest number of all the complaints reaching the health authorities deal with real or supposed nuisances. There seems to be a widespread belief that the chief function of the health officer is the abatement of nuisances. Formerly the health officer was a general scavenger and his main duties consisted in looking after nuisances. Nuisances often clog the health office and crowd out more important sanitary and hygienic matters. In most complaints the question at issue is whether the nuisance exists or not—a question of fact which could be decided just as well by the police courts as by a board of health or health officer. However, the abatement of nuisances is usually assigned to the health authorities by statutory enactment.

In a few cities, especially those with liberal charters, the ordinances

<sup>10</sup> Utah, Chapter 45 of 1889, Sec. 1.

covering nuisances are so definite and explicit that an inspector may determine a nuisance and issue an order for its abatement. In cases where condemnation of property of considerable value is involved, such for example as when an offensive trade is alleged to be a nuisance, it is usually necessary to prove the case in court before the nuisance can be abated. In court, substantial injury must be shown and the health officer should be sure he has the facts as to the nuisance before he appears in court. He will be required by the court to establish the source, frequency, and nature of the odors, or whatever is alleged to be the nuisance. It is exceedingly difficult to establish the fact that many nuisances are dangerous to the health of the community and the cause of sickness.

In general two methods are followed for the control of nuisances: (1) prevention; (2) abatement. The first is the wisest and aims to regulate and control the different conditions likely to cause a nuisance or even to prohibit them. The second merely provides legal steps for their abatement. There are at least four ways in law of dealing with nuisances: (1) By criminal action; (2) by injunction; (3) by damages (private suit); (4) by abatement under statutory powers.

## FACE MASKS

*Face masks* have a certain degree of usefulness in limiting the spread of infections transmitted by the secretions from the mouth and nose. They act mechanically to check the diffusion of infectious secretions by the patient, or they may be used by well persons (recipients) as a barrier against such infections. They are especially indicated in serious diseases such as pneumonic plague, diphtheria, scarlet fever, pneumonia and other malignant infections transmitted by droplets.

Face masks have long been in successful use by surgeons to guard against droplet infection of wounds. They are also useful to physicians in throat examination, and to protect nurses, orderlies and others about patients. The mask may be worn either by the patient, the recipient, or both.

During the influenza epidemic of 1918 face masks came into vogue as a public health measure to check the spread of this disease. The wearing of masks was made compulsory in San Francisco and other California cities. This measure, however, had no noticeable influence upon the course of the epidemic. Theoretically this measure seems sound, but in practice it is disappointing, for there are many loopholes. Droplet infection is only one of the ways by which these diseases are spread; in fact, droplet infection probably accounts for only a small percentage of cases—other modes, such as hand to mouth infection, various forms of contact, spoons, cups and table ware, etc., explain

the transfer in most cases. The gauze mask, furthermore, has many imperfections of construction and technic of wearing.

For complete protection the eyes of the recipient must also be guarded. Microorganisms landing upon the conjunctiva may find their way to the nose in 5 minutes and to the throat within 15 minutes. Weaver<sup>11</sup> insists that the mask must be properly constructed with 3 or 4 layers of butter cloth (not gauze or cheese cloth) and held by a wire frame so as not to touch the lips and nose. Kelloy and MacMillan<sup>12</sup> state that when the mask has a sufficient degree of density to be a useful filter, breathing is difficult and leakage takes place around the edge of the mask. Doust and Lyons<sup>13</sup> used *B. prodigiosus* to determine the danger zones and permeability of various masks, and found masks of medium gauze, 2 to 10 layers, worthless; but masks of 3 layers of butter cloth effective.

The face mask has a limited usefulness. It has not been demonstrated to have that degree of efficiency to warrant compulsory application for the checking of an epidemic. Even when masks are used by doctors and nurses at the bedside, this should not lead to the neglect of measures necessary to prevent the spread of infections by hand to mouth and other means.

## DRUG ADDICTION

The chief habit forming drugs are alcohol; opium and its alkaloids, especially morphin, codein, and heroin; and cocain. It has only recently been realized that drug addiction is an important public health problem, in addition to its sociologic and economic aspects.

It is conservatively estimated that 1 per cent. of the population of the United States, or at least one million persons are drug addicts (excluding alcohol). The slums and the vice districts of cities give the largest pro-rata indulgence in drugs. Blair reports that in Pennsylvania there is more free and unrestricted addiction in small places than in large cities. The age of addicts ranges from 12 to 75 years. Many heroin<sup>14</sup> addicts are boys and girls under 20 years of age. Anyone repeatedly taking a narcotic drug for thirty days is in grave danger of becoming a slave to the drug. The reasons for beginning the vicious practice are innumerable. In most cases, however, once learned, there is an underlying defect or weakness, either acquired or inherited, that chains the victim to the vice. The Harrison law meets the situation only in small part.

<sup>11</sup> *Jour. Am. Med. Assoc.*, Oct. 12, 1918, and *J. Infec. Dis.*, XXIV, 3, March, 1919, p. 218.

<sup>12</sup> *Am. J. P. H.*, Jan., 1920, X, 1, p. 34.

<sup>13</sup> *J. A. M. A.*, Oct. 12, 1918.

<sup>14</sup> Heroin should be eliminated from all medicinal preparations and should not be administered, prescribed or dispensed. The importation, manufacture and sale of heroin should be prohibited.

More aggressive and absolute measures are necessary to combat this growing and serious habit, which undermines health and interferes with efficiency and character of a very large number of persons. See also page 433.

### ALCOHOL

**Alcohol.**—Ethyl alcohol ( $C_2H_5OH$ ) has been used since the dawn of history. Until recently, we had little precise knowledge concerning the effects of alcohol. No one doubts that alcohol is harmful when used in amounts sufficient to produce its full physiological effects. In sufficient concentration, it is a poison to all living matter, both animal and vegetable. The question in dispute is upon the effects of "small" amounts. Alcohol is a solvent for many substances, is locally irritating, is quite volatile, and has other well defined physical and chemical properties, but perhaps the most striking characteristic is that "it is equally inflammable whether one touches a match to it or writes about it."

**Local Irritating Action.**—Applied to the skin in sufficient concentration (60 to 90 per cent.), alcohol produces redness, itching, and a feeling of heat like other volatile and irritant substances. Upon wounds a concentrated solution causes a precipitation of the proteins and acts first as an astringent and then as a corrosive. The effects of alcohol on mucous membranes are similar to those on wounds.

**Alcohol as a Food.**—Whether alcohol can be regarded as a food or not, depends upon the definition of a food. Alcohol is not a tissue builder, but within limits it is burnt in the body and thus furnishes heat and energy. In this sense, then, alcohol is a food. Thus, one gram of alcohol furnishes seven calories of heat when burned. The human body is not able to burn more than about two ounces of alcohol a day. If more than this amount is taken, it promotes the storage of fat. The excess alcohol is eliminated unchanged in the urine and by the skin and lungs.

Alcohol may be compared with sugar and starches as a food—both are oxidized in the body and furnish heat and energy, but there is this difference: sugar and starch help to repair waste, which alcohol cannot do.

**Effect upon Digestion.**—Alcohol in the mouth causes a very appreciable secretion of saliva, presumably by reflex action. It is not unlikely that the taste has some influence on this result; in those who enjoy the taste of alcohol, it induces a more rapid secretion and an immediate digestion; while in those to whom it is disagreeable, the effect is less marked.

Small amounts of wines and liquors used as a condiment to flavor sauces and desserts are pleasing to the taste of many persons, and thus

used probably stimulate the appetite, and through the psychic effect of savory morsels promote the secretion of digestion juices.

The augmentation of the activity of the digestive ferments caused by alcohol is so slight in any case that it does not seem likely that it plays any important rôle in digestion.

All are agreed as to the deleterious action of any but moderate doses of alcohol on digestion. Large quantities irritate the stomach and may lead to profuse secretion of mucus, nausea, and vomiting—irritative gastritis.

**Action on the Nervous System.**—The action of alcohol on the nerve centers seems to differ in individuals, but this is solely a difference of manifestation, for the physiological action is essentially the same in all persons. In small quantities, it produces a feeling of well being and goodfellowship, along with increased confidence in physical power and mental ability. This confidence, however, is due to removal of repression and inhibition. Larger quantities are followed by laughter, loquacity, gesticulation, and other indications of animal excitement. The face becomes flushed and heated, the eyes brighter and livelier, and the pulse quickens. Even at this stage, self control is partially lost, and the will power is weakened. The speech may be brilliant, but often betrays the speaker. The movements are more lively, but they are often undignified. The loss of self control is often indicated further by furious outbursts of anger or unreasonableness, or by the indulgence in maudlin sentimentality and sensual fancies. The sense of responsibility and the power of discrimination between the trivial and the important are lost, and the individual has no regard for the feelings of others or the ordinary conventions of life. If more alcohol is imbibed, the movements become uncertain, the speech becomes difficult and stammering, the walk becomes a stagger, and a torpid slumber follows. Often nausea and vomiting set in, doubtless due to the direct irritating action on the gastric mucosa. On recovery from slumber, a very great depression is generally suffered, together with nausea and vomiting and want of appetite, which may last several days, and is associated with all the symptoms of acute gastric catarrh. Very large quantities of alcohol produce total unconsciousness, resembling chloroform anesthesia. If unconsciousness lasts longer than ten to twelve hours, recovery seldom takes place.

On the lower part of the central nervous system, alcohol acts as a distinct depressant, for the coördination of movements suffers at an early stage. In the spinal cord, there is a depression of the reflex, which passes into complete paralysis. The medulla oblongata is the last part of the central nervous system to be acted on by alcohol. Dodge and Benedict find that alcohol depresses the lower centers most and the highest centers least. It retards the reaction time. In one sense, alcoholic depression may be regarded as a conservation process.

Alcohol is a nerve poison; hence, alcoholic neuritis is well known to the clinician. The repeated use of excessive amounts of alcohol causes brain injury, as Korsakoff's disease, alcoholic hallucinosis, delirium tremens, and other forms of alcoholic insanity.

Alcohol psychoses account for about 12 per cent. of all first admissions to hospitals for the insane. They occur about three times as frequently in men as in women, and in general the subjects come more frequently from the cities than from rural districts.

**Alcohol as a Stimulant.**—Alcohol acts like ether and chloroform and other narcotic drugs. There is a preliminary stage of excitement, mental confusion, and often excessive and incoördinate activity.

Binz and his pupils claim that alcohol first stimulates and then depresses the nervous cells, but the preponderance of evidence is clearly in favor of the views of Schmiedeberg, Bunge and their followers, that it depresses the central nervous system from the beginning. The apparent excitement is not due to true stimulation of the motor areas, but is the result of these areas being freed from control by the weakening of the highest powers of the brain—the will and self restraint. Even the smallest quantities of alcohol tend to lessen important activities of the brain, for the drug acts first upon those qualities which have been built up through education and experience.

One of the most deceptive of experiences is the false sense of stimulation which alcohol gives. By depressing the higher cerebral centers, it releases the lower mental processes. Hence, its first effect is to cloud the judgment and dull the finer feelings. It takes off the brake of restraint, loosens the tongue, and sets free the lower animal passions. It is this blunting of the higher and finer mental powers which causes people to say things and do deeds under the influence of alcohol that would shock their sensibilities otherwise.

It is difficult to measure the harm done by this effect of inhibiting the nobler mental functions, but it must be great. Alcohol does not relieve fatigue, but makes one unconscious of fatigue.

**Effect on Efficiency.**—A large number of tests have demonstrated that the apparent quickening of the mind and body under alcohol are false sensations. The performance of difficult operations involving muscular coördination and judgment are slower and less accurate under alcohol than normally. It is difficult, on account of the feeling of confidence that comes from alcohol, to convince a typist, a sharp shooter, or type setter of this fact until shown the records. Even amounts of alcohol so small that the subject and observer are not aware of any abnormality of appearance or behavior, interfere with efficiency.

It has been found that regiments not supplied with alcohol march farther and are in better condition at the end of the day than others to which it has been given. The experiments of Durig lead to the same

results, the total amount of work being smaller under alcohol, and the expenditure of energy greater. Forms of work requiring intelligence are performed less correctly with alcohol than without it; thus, type setters can do more work and make fewer mistakes when they abstain from its use. Even Binz, who claims that alcohol is a primary stimulant, admits that this action is transient, and is followed by depression, so that the total amount of work may thus be reduced. Kraepelin found in a series of careful measurements of the simpler processes, that the responsive powers were weakened by very small quantities of alcohol, while the motor functions seemed to be facilitated by small, and retarded by large quantities. For example, a person under even a small dose of alcohol makes more errors than usual in adding a row of figures, or in reading a series of unconnected syllables. Of special importance is the fact that the subject of the experiment is quite unaware of the inferiority of his work, and believes it to be unusually good. Kraepelin has shown that even about a pint of beer will lower intellectual power, impair memory, and retard the simpler mental processes. Kraepelin's latest investigations tend to show that this effect of alcohol lasts much longer than is generally recognized, the mental equilibrium being reinstated only after 12 to 24 hours after even moderate indulgence. In fact, alcohol may be found in the blood 24 hours after its ingestion.

We have the authority of Connie Mack that alcohol spoils a good baseball player. He said in 1910, a year that the Philadelphia Athletics won the world's championship, that fifteen of his twenty-five players did not even know the taste of alcohol.

**Pulse, Reflex, and Temperature.**—The *pulse* is accelerated during the stage of excitement, but this is due to increased muscular effort, and not to any direct stimulating action on the heart. There is at first a slight rise in blood pressure in some cases, but large quantities affect the heart in the same way as ether and chloroform, weakening the auricular and ventricular beat, and inducing dilatation and slowing of both chambers.

The flushed, perspiring face of the alcoholic is familiar. This indicates dilatation of the skin vessels, which is sometimes accompanied by a slight contraction of the internal organs. This effect of alcohol causes a sense of warmth and comfort, which underlies the popular belief that it is helpful to take alcohol when braving exposure to cold and damp, during a chill, etc. Here again our sensations are misleading guides, for the temperature of the body may fall one degree C. while the skin is flushed with a sense of warmth. This is due to excessive heat loss through conduction and radiation, and also to the fact that the heat regulating mechanism is rendered less sensitive by alcohol. Hence, alcoholics (when inactive) may freeze to death when the temperature is scarcely at the freezing point.

The changes in the respiration induced by alcohol are too small and too inconsistent to be of any special importance.

**Alcohol and Venereal Disease.**—Alcohol is the bedfellow of syphilis and gonorrhea. It is intricately interwoven into the warp and woof of sex hygiene. The story of many cases of sexual immorality begins with the influence of drink. Alcohol is generally accredited with increasing sexual desire, although we have the authority of Shakespeare that it interferes with the consummation of sexual intercourse. The unquestioned sexual excitement is not due to stimulation of the generative organs, but to the loss of self control and the anesthetic action of alcohol upon the higher centers of the brain.

**Resistance.**—It has long been known clinically that persons addicted to the use of alcohol show less resistance to certain diseases and to operations accompanied by shock, than more temperate individuals. In very intemperate persons, the prognosis must be guarded in an attack which would ordinarily be accompanied with little danger. "Drunkards have a very slim chance of recovery when attacked by pneumonia" (Osler).

When animals are subjected to treatment with alcohol, and then inoculated with pathogenic microorganisms, the results invariably show a greater susceptibility to infection and a greater mortality than in control animals. A similar effect is produced when toxins are injected instead of bacteria. The reason for this reduced resistance is not clear. It may result from inactivity of the leukocytes (Rubin), or a reduction in the hemolytic complement (Abbott and Bergey).

The tolerance to alcohol is not so great as that acquired for morphin and nicotin.

Life insurance figures plainly show that even the moderate use of alcohol tends to shorten life.

**Accidents.**—Accidents often happen under the influence of alcohol. Many automobile wrecks and railroad collisions can be traced to the recklessness of the drinker. Figures show that industrial accidents are more frequent in those who drink than in abstainers. It is regarded as significant that three such accidents occur on Monday to two on other days.

According to three insurance companies, the following percentages of accidents are attributed directly or indirectly to alcohol:

Railroad accidents .....	7	per cent.
Street cars .....	8	" "
Automobiles .....	10	" "
Vehicles and horses .....	8	" "
Heat and sunstroke .....	43	" "
Machinery .....	7	" "
Mines and quarries .....	8	" "
Drowning .....	13	" "
Gunshot .....	10	" "

**Poverty.**—There would be much less poverty, crime, misery, and distress in the world without alcohol. It is not the sole cause of these ills, but a potent factor. The social and economic aspects of the alcohol question are plain to every social service worker. Of 352 able-bodied men who failed to support their families in Boston, 65 per cent. (243) were drunkards.<sup>14a</sup> About 25 per cent. of cases that come to charitable organizations, and about 37 per cent. of poverty found in almshouses give an alcoholic history.

Three fourths of the cases of children cared for by the Chicago Juvenile Protection Association in 1911 grew out of alcoholism in the parent or guardian.

**Crime.**—Crime is often committed while under the influence of alcohol. A large percentage of criminals have an alcoholic history. The relation between alcohol and crime is not disputed, but it is difficult to express its influence in precise percentages. Drink was said to be the sole cause of crime in 16.8 per cent. of 13,402 convicts in 12 states of the United States studied by the Committee of Fifty. Further, drink contributed to 49 per cent. of the crimes against property; 51 per cent. of the crimes against person; and 47 per cent. of all other crimes.

The first action of the police in a local uprising is to close the bars, and a noteworthy act of much good in the stress of the World War was to check the use of alcohol. Alcohol is a handicap for a nation in peace or war; it is also a handicap for an individual in the struggle for existence.

**Heredity.**—The relation of alcohol to heredity is difficult to appraise. Experiments upon lower animals give various results, but indicate lowered vitality in the offspring. The craving for drink is not transmitted, but mental deficiency with weakened will power that may express itself in intemperance is inherited. Many alcoholics are also defectives and transmit the mental defect. This subject is fully discussed on page 430.

**Alcohol in Medicine.**—Occasionally alcohol is useful in the treatment of diabetes, where it may partly replace fats and carbohydrates when these are harmful. It is no longer considered good practice to use it as a stimulant in fevers, septic, and debilitated states. At the Massachusetts General Hospital, the amount of alcohol used for the patients fell 70 per cent. from 1897 to 1906.

It may be a serious mistake in first aid to induce persons who have fainted, or who have been injured, or who have lost consciousness, to drink brandy or whiskey.

**Uses of Alcohol.**—Because alcohol produces a fictitious sense of well-being, disguises fatigue, and smothers worry, it has been widely used by elderly persons and certain individuals, particularly convalescents and

<sup>14a</sup> Report of the Boston Associated Charities, 1910.

those upon whom life bears heavily. Alcohol is used in such cases for its physiological effect of partially benumbing the sensibilities and creating an artificial sense of well-being. In such situations, the use of alcohol often seems desirable, although not entirely devoid of danger, especially of starting the habit in the young.

In some cases the depressing action of alcohol may be a conservative process, although the magnitude of the harm from its widespread abuse outweighs this theoretical advantage.

**Summary.**—The student of Preventive Medicine regards the alcohol question as a major public health problem. Alcohol is a habit-forming drug; it lowers resistance and shortens life, impairs efficiency, promotes poverty, increases crime, favors accidents, excites passion and diminishes self-control; it leads to immorality and tempts venereal infections. Alcohol increases economic waste and retards social progress. It is not a stimulant. Its local irritating action and its toxic effects upon nerve tissue account for a certain amount of harm; but the greatest harm perhaps results from the fact that alcohol, even in small amounts, clouds judgment, depresses will power, and takes the check off self-restraint. In short, it stupefies the highest and noblest functions of the mind.

#### SANITARY SURVEYS

Sanitary surveys are designed to determine the general sanitary and hygienic conditions of a community. Surveys are often made to discover one or more special factors; thus we have tuberculosis surveys, school surveys, privy surveys, milk surveys, water shed surveys, housing surveys, etc. Survey means "to look," and the conclusions must be based on facts obtained by observation.

The following is an outline of the sanitary survey used by my students in the School of Public Health and also in the Harvard Medical School.

<sup>14b</sup> Abderhalden: *Bibliographie der gesamten wissenschaftlichen Literatur über den Alkohol und den Alkoholismus*. Berlin and Vienna, 1904.

<sup>14c</sup> Viazemsky: *A Bibliography on the question of alcoholism*. Moscow, 1909. Part I (Russian). The Russian original, together with an English translation made by H. A. Norman and H. B. Dine, are both on file at the Nutrition Laboratory.

*SANITARY SURVEY OF A CITY OR TOWN*

Each student is required to make a sanitary survey of a city or town, based on the following outline, and submit a written report of the same. The report should consist of (a) *data*; (b) *interpretation* of the facts, and (c) *criticisms* and *recommendations*.

**Introduction.**—General description of the town including: (a) History. (b) Geographical position. (c) Topography. (d) Geology. (e) Climate. (f) Population (number and constitution). (g) Urban, suburban, or rural. (h) Other information about the town. (i) Organization of the board of health.

**Water.**—(a) The water shed—Sources of pollution, methods of collection, storage, purification. (b) An analysis of the water and its interpretation. (c) Public or private wells. (d) Examine a sample of the water in the laboratory.

**Sewage.**—(a) System of disposal—if purified or treated, how? (b) Efficiency. (c) Relation to health of this and other towns. (d) Criticism of system.

**Garbage, Refuse, Ashes.**—(a) Method of collection. (b) Disposal. (c) Relation to health. (d) Criticism of methods.

**Vital Statistics.**—(a) Death rate. (b) Infant mortality. (c) Specific rates for: (1) Typhoid; (2) tuberculosis; (3) measles; (4) scarlet fever. (d) Submit samples of blanks used by the department of health, especially those for deaths, births, marriages, and notifiable diseases. Fill out a death certificate and a birth certificate. State opinion as to thoroughness of reporting morbidity, mortality, and other vital statistics.

**Milk.**—(a) Report on the sanitary conditions of one farm and one city dairy, using score cards. (b) Amount of milk "certified." If possible, visit and report on farm producing it. (c) Examine a sample of the milk in the laboratory. Interpret result.

**Sanitary Nuisances.**—(a) Sources of odors. (b) Dust—causes and method of prevention. (c) Rubbish and general cleanliness. Empty lots. Dumps. (d) Flies and mosquitoes. (e) Rats and vermin. (f) Stables and manure. (g) Breeding places of mosquitoes. (h) Smoke. (i) Unnecessary noises. (j) Piggeries, etc. (k) Legal definition of "nuisance" and method of abatement.

**Industrial Hygiene.**—(a) Report upon one industry based upon a visit to a factory or workshop.

**Housing.**—(a) Sanitary condition of one tenement. (b) Ventilation of one large building.

**Infectious Diseases.**—(a) Give a list of the diseases, notification of which is required by the board of health. (b) Quarantine regulations. (c) Methods of disinfection and fumigation. (d) What measures are

taken to prevent the spread of tuberculosis? (e) Should some other disease be prevalent what measures are taken to control it? (f) Venereal diseases, reporting and control.

**Schools.**—(a) Visit and report on one school—ventilation, lighting, temperature, playgrounds, etc. (b) Medical inspection of school children. How conducted? (c) Diseases for which children are excluded from school.

**Miscellaneous.**—(a) Markets. (b) Provision stores and soda fountains. (c) Slaughter houses and meat inspection. (d) Cold storage plants. (e) Kitchens of hotels and restaurants. (f) Wharves. (g) Barber shops. (h) Distribution of educational and other pamphlets. (i) Other activities of the board of health, as maintenance of diagnostic laboratory, meat inspection, etc. (j) District nursing and social service. (k) Charitable institutions or organizations of importance to public health. (l) City planning. (m) Food and drug administration.

**General Summary of** (a) Conditions found. (b) Criticisms. (c) Recommendations.

## MANAGEMENT OF AN EPIDEMIC CAMPAIGN

**The Management of an Epidemic Campaign.**—The first essential for success in the suppression of an epidemic is a knowledge of the epidemiology of the disease. The most important single fact from a practical standpoint is a knowledge of the mode of transfer of the infection. Before we knew the cause of yellow fever, yellow fever campaigns were crowned with success because we knew it was transmitted through the bite of a mosquito. We know the cause of cerebrospinal meningitis, but there are still uncertain factors concerning its mode of transmission, and, therefore, our efforts against this disease have been unavailing. The established fact that hookworm disease is transmitted by the larvae through the skin is of vital importance in the control of this disease. Without this knowledge at least 90 per cent. of our efforts to repress hookworm disease would be wasted. When typhoid fever was regarded as a water-borne infection only partial success was achieved because contacts, milk, flies, and other modes of transference of the typhoid bacillus were disregarded.

In case the disease has an intermediate host or the virus is transferred by an insect or other animal, a knowledge of the biology of the animal in question is of prime importance. For example, the habits and habitat of the yellow fever mosquito are quite different from those of the malarial mosquito. A campaign against the rat and flea without an acquaintance with their breeding and feeding places and the best means available to repress or suppress such vermin would be unsuccessful. The same is true in our campaign against tuberculosis with reference to cattle and man; in rabies with reference to dogs and other

mammals; in sleeping sickness with reference to the tsetse fly; in Texas fever with reference to the tick; Malta fever with reference to the goat; relapsing fever to the bedbug, and typhus fever with reference to the louse, etc.

*Authority.*—Proper authority is necessary in order to enforce the necessary measures. This authority may come from the municipality, the state, or the federal government. In localized outbreaks, municipal authority is sometimes sufficient. More frequently the wider authority of the state is desirable. In our country it is a recognized principle of government that the enforcement of health laws and regulations belong to the *police powers* of the *individual states*. In most instances the interstate powers of the federal government are essential, especially as interstate problems are almost always involved in epidemic outbreaks. The federal authority is limited in health matters by the constitution. It therefore cannot act within a state unless invited to do so by the duly constituted authorities of the state. To send government health officers into a state against the will of the state corresponds to the sending of the regular army into a state to enforce measures against the will of the governor of that state. Such extreme measures are, therefore, only taken in times of emergency. Occasionally a state, refusing to take necessary action and protect the other states, is quarantined. Thus, when California refused officially to recognize the existence of plague in 1899, the federal government quarantined the entire state. On account of our dual form of government it is important that the federal government, the state, and the local authorities cooperate in a friendly spirit. Epidemic diseases recognize no geographical boundary, and energetic and cooperative action is always called for to suppress an outbreak.

It is the common experience of those who have to deal with epidemics that there is usually insufficient authority in law to provide for an emergency. It is, therefore, often necessary to take the bit in the teeth and adopt arbitrary measures which usually have the support of the community. Advantage may be taken of an epidemic to obtain laws to improve the health organization or the powers of the health officer. In this way an epidemic serves a useful purpose in arousing action.

In the conduct of an epidemic it is very important that all the authority should center in one person. To conduct an epidemic with a board of health or a health committee or a commission of any kind invites failure. It would be just as foolish to have a board of generals to fight a battle. Those who have been through many epidemics realize that it is no figure of speech to compare an epidemic campaign to a battle. It is a fight carried on at high tension, and, although the foe is invisible, it is war in every sense of the word. The casualties often outnumber the bloodiest conflicts,

*Ways and Means.*—It is impossible to carry on a successful campaign against an epidemic without material resources. An epidemic campaign is expensive and success depends upon generous support. In most of the campaigns against yellow fever, plague, and cholera that have been waged in this country the expense has been borne in part by the federal government, in part by the municipality or state, and in part by private subscriptions. The government has an epidemic fund appropriated by Congress and which is usually kept at about a million dollars. This fund is available for plague, yellow fever and cholera, or other diseases specifically stated in the appropriation bill.

*Organization.*—Headquarters should be organized in a convenient part of the city or the infected area, and such quarters should have all the modern office equipment and transportation facilities necessary for the quick dispatch of business. The city is then divided into sanitary districts. These may correspond to the political wards or the police districts and a subordinate is placed in charge of the work in each district. These districts are known as sanitary divisions, and the officer in charge of each division must establish headquarters for the work of that division. The actual work is done from division headquarters, under the direction of the chief in charge of the epidemic.

It is also necessary to establish a laboratory in case laboratory diagnosis is necessary for the recognition of cases or carriers, and emergency hospitals and detention barracks must be provided. Few cities have sufficient hospital facilities to meet a sudden emergency. Temporary arrangements must therefore be made. A modern school building makes a very good hospital and may be equipped for the reception of patients at short notice. Various squads must now be organized to carry on the particular work at hand. In the case of yellow fever these will be mosquito brigades; in the case of plague, rat brigades and disinfectors, and in the case of smallpox, vaccinators, etc.

It is frequently desirable, in fact often necessary, to make a house to house inspection throughout the infected district in order to collect certain data, to determine whether cases are being reported or hidden, and to carry out special measures. These house to house canvasses are under the immediate direction of the officer in charge of the sanitary district and should be repeated as often as the occasion may demand.

It is essential that all cases or suspected cases of the disease be promptly reported, for a case of communicable disease known is a case neutralized. It is the missed cases and the hidden cases that are particularly dangerous.

*Education.*—A campaign of education should be carried on at the same time that the disease is being attacked. The people are keenly alive and hungry for information. Well-worded articles in the news-

papers, circulars, pamphlets, lectures, demonstrations, and the other usual methods are available. The education of the community is important in order to obtain coöperation, for it is a handicap to fight an epidemic without the active support of the people. While the first duty of the officer in charge is to allay panic and calm the unreasonable fears of the stricken community, the opposite extreme must be avoided. A healthy fear of the disease is one of the best instruments in the armamentarium of the sanitarian. It is almost hopeless to make progress against disease where the people supinely accept the conditions. Thus, if the people of the United States feared typhoid fever as they do yellow fever, it would soon diminish to the vanishing point.

## QUARANTINE

The word "quarantine" is derived from the Italian word "quaranta," meaning forty. Its present-day meaning dates from the middle ages when Venice and other Hanseatic cities detained arriving ships with cases of pestilence aboard for a period of forty days. This was the first systematic application of maritime quarantine, although from the earliest times lepers were segregated as unclean. To-day we have many kinds of quarantine: maritime quarantine, interstate quarantine, house quarantine, cattle quarantine, yellow fever quarantine, "shotgun" quarantine, etc.

A technical distinction is now drawn between quarantine and isolation. *Quarantine* refers to the detention of well persons exposed to infection for the period of incubation of the disease. *Isolation*<sup>14a</sup> refers to the segregation of the sick and carriers. The terms are often used interchangeably. Precise knowledge has greatly lessened the rigors of quarantine, which aims only at sanitary isolation.

The dominating principle in modern quarantine is that it must be a sieve or filter and not a dam. All quarantines based upon the principle of the Chinese wall are doomed to fail. The object of quarantine is, then, to destroy, detain, or isolate infection with the least possible hindrance to trade and travel. The art consists in regulating the openings in the quarantine sieve so as to hold back certain infections, but permit all else to pass. Maritime quarantine may be regarded as a coast defense against exotic pestilence, a defense which guards against an invisible foe oftentimes more damaging than hostile armies and navies.

The cure for quarantine is sanitation. Thus, if all communities, especially seaports, were to place their cities in the best sanitary con-

<sup>14a</sup> See page 499.

dition in accordance with the teachings of modern science, there would be little danger of disease spreading to epidemic proportions and very little need of maritime quarantine. If the ports in our southern littoral would free themselves of the *Stegomyia* mosquito they could laugh at yellow fever. A city containing few rats could not have an epidemic of plague. A port supplied with a pure, well-protected water supply need not fear a water-borne epidemic or cholera. A thoroughly vaccinated community runs no hazard from smallpox. Typhus fever could not spread in a community with cleanly personal habits, that is, one free from lice and other vermin.

### ISOLATION

In theory isolation is the most perfect single method to check the spread of a communicable disease. The results in practice, however, have been somewhat disappointing on account of unusual difficulties. The statement has frequently been made, especially with reference to typhoid fever, that if all the cases could be isolated (which includes the disinfection of the discharges) we would soon see an end of the infection. We now know that this statement is not true, on account of the bacillus carriers and the mild and unrecognized or "missed" cases. Because the isolation of the reported cases represents only a portion of all the foci of infection and, therefore, at best could not in itself control an epidemic disease, discredit has been thrown upon this procedure, which is one of the essential features of all systems of prevention. As a matter of fact, it has been shown that in certain diseases, like measles, which is communicable for three days or more before the nature of the disease is recognized, isolation has practically no influence in diminishing the prevalence of this widespread infection. It is true ordinarily that a case of measles does most harm before it is isolated; nevertheless, this is no reason why it should be permitted to endanger the community further. The value of isolation is also diminished by the prevalence of carriers. In fact, its practical usefulness in a given infection is inversely proportional to the number of carriers.

If each case isolated prevents on the average only one other fresh infection, there would still be justification sufficient to continue the practice. As a matter of fact, the practical value of isolation varies with each disease, depending upon the degree of its communicability, the time when it is communicable, the promptness by which it may be recognized, the modes by which it is transferred, the existence of latent infections, missed cases, carriers, and other factors which influence the spread of the infection.

Young<sup>15</sup> reports the results obtained from three degrees of isolation in the home:

A—Isolation with trained attendant.

B—Isolation without trained attendant.

C—Impossible to isolate for lack of room for exclusive use of the patient.

It was found in the case of scarlet fever 1.087 per cent. of secondary cases occur in Class A, 5.22 per cent. in Class B; and 6.9 per cent. in Class C. Cases cared for in hospital showed 2.32 per cent. of secondary cases. In the case of diphtheria there were no secondary cases in Class A; 1.18 per cent. in Class B; 4.88 per cent. in Class C; and 0.15 per cent. in those treated in hospital. These figures clearly show that the value of isolation depends upon the intelligence and care with which it is carried out.

The degree of isolation varies markedly with the different infections. A case of yellow fever may be isolated under a mosquito screen, and a case of diphtheria or scarlet fever may be effectively isolated in a bed in a general ward, provided intelligent and painstaking care is exercised to destroy the infection as it leaves the body. Isolation of the more readily communicable diseases, as smallpox and measles, should be much more absolute. Typhoid bacillus carriers need not be imprisoned. It is sufficient to limit their activities, especially to prevent their occupation in kitchens, dairies, or about foodstuffs. There is no good reason to isolate a consumptive or leper without open lesions—that is, cases in which the bacilli are imprisoned in the tissues and not discharged into the environment. A careful consumptive or leper may be allowed a wide latitude. On the other hand, isolation in chronic infections, such as tuberculosis and leprosy, with open lesions, is the most helpful and at the same time the most difficult single procedure we have to control their spread. The careless, indigent, ignorant, or helpless consumptive is a public menace that needs energetic and sometimes arbitrary isolation.

Isolation may most readily and effectively be carried out in hospitals or sanatoria. Proper isolation in the home requires a special room or rooms, intelligent nursing, appliances for disinfection, etc., a combination often difficult to arrange. House quarantine varies with the different diseases. To carry it out rigorously in all cases and under all conditions is folly. Different diseases need different procedures. Sometimes it is sufficient simply to placard the house as a warning. At other times it may be necessary to station sanitary guards about the premises to enforce the quarantine. The imperfections of strict isolation by the "shutting in of houses" are graphically described in Defoe's "Journal of the Plague Year."

<sup>15</sup> *Jour. A. M. A.*, Feb. 6, 1915, LXIV, 6, p. 488.

Isolation camps or temporary barracks in times of epidemics are effective measures in checking the spread of some infections. This method has proved effective in actual practice in the case of smallpox, yellow fever, plague, cholera, and other diseases.

It often becomes a difficult question to determine whether the well members of a household should also be quarantined—especially whether the well children should be permitted to attend school. This perplexing question must be decided for each disease separately, and the decision in each disease is sometimes modified by attending factors. Usually the other children in the family in the case of scarlet fever are excluded from school for four weeks from the beginning of the last case. In most cities the same rule holds for diphtheria, although here we are able to determine whether the children are bacillus carriers or not. At least two negative cultures from the nose and throat should be required before such children are allowed freely to mingle with other children. The principal factors which determine whether the well children in a family shall be permitted to attend school or not in any particular infection rests upon our knowledge as to whether the disease is conveyed by a third person and the frequency of bacillus carrying and of missed cases.

Isolation becomes one of our most valuable public health measures when communicable diseases affect persons working about milk, meat, and other foods capable of conveying infection.

One of the practical objections to isolation and one reason that it meets with so much opposition from the public is that the compensation of the wage earner ceases through no fault of his own. It is evidently unjust practically to imprison and punish a wage earner for the good of the community, because he or some member of his family has contracted an infection, perhaps through some fault of the community itself. It is, therefore, reasonable and just that wage earners at least should be compensated and their personal interests safeguarded during enforced isolation.

In practice, isolation only reduces to a moderate degree the prevalence of disease. The limitations of this valuable procedure are now well understood. With improved methods of diagnosis and increased knowledge of the methods of the spread of disease, isolation will be made increasingly effective. Every case isolated is a focus of infection neutralized. Although not as satisfactory in practice as it is in theory, isolation will ever remain one of the chief administrative procedures for the control of the communicable diseases.

In the past, geographic isolation was one of the safeguards of the people against disease, but in modern times, since all means of transportation have improved, and communication has become more extended and more rapid, the diffusion of infection is facilitated.

*MARITIME QUARANTINE*

Maritime quarantine in this country is enforced only against six diseases, viz., cholera, yellow fever, plague, typhus fever, smallpox, and leprosy. We do not quarantine against typhoid fever, tuberculosis, measles, and other infections which are not greatly feared and which are constantly with us. Infections of a non-quarantinable nature, such as scarlet fever, measles, etc., arriving at a port are permitted to enter, but must then comply with the local laws and regulations.

The period of detention is based upon the usual period of incubation for each disease and is as follows:

Cholera .....	5 days.
Yellow fever .....	5, sometimes 6 days.
Plague .....	7 days.
Typhus fever .....	12 days.
Smallpox .....	14 days.
Leprosy .....	not admitted.

The time of detention is usually counted from the completion of disinfection or at least from the last possible exposure to the infection. This is usually not a very difficult matter for the quarantine officer to decide, but in case of doubt the public is given the benefit.

At well-equipped stations where laboratory facilities are available it is not necessary to detain cholera contacts for the full period of incubation. Stool examinations for vibrios will furnish reasonably dependable evidence upon which to hold or release those persons who have been exposed to infection. In the case of smallpox, those who have had the disease or have recently been successfully vaccinated need not be detained.

No communication is permitted with a vessel in quarantine excepting under supervision of the quarantine officer; that is, no one is allowed to board the vessel or leave it, and nothing is allowed to be thrown overboard, taken ashore, or brought on board without the express permission of the quarantine officer. These restrictions apply alike to foods and to supplies and merchandise of all kinds.

The vessel itself may be disinfected and furnished with a fresh crew and released from quarantine while the passengers and crew are detained in suitable barracks. Vessels trading with infected ports should carry immune crews; that is, persons who have either had the disease or have been rendered actively immune through one of the vaccines or viruses.

When a quarantinable disease breaks out on board a vessel it is of practical importance for the quarantine officer to determine whether the infection was contracted on board the vessel or on land. In the first case the vessel must be regarded as infected and the measures used for its purification are much more exacting than in the second case. Thus, if

plague breaks out within seven days from the time a vessel leaves an infected port, and no other case occurs, it is exceedingly probable that the patient contracted his disease ashore and was in the period of incubation when he came on board. If, however, plague breaks out after seven days, and especially if secondary cases occur, it is evident that the ship itself is infected. The same reasoning applies to yellow fever and the other communicable diseases.

The measures taken at quarantine to keep out these diseases depend upon an accurate knowledge of their cause and mode of transmission. Briefly summarized, the measures applicable in each case are as follows:

#### CHOLERA

The sick are removed from the vessel and isolated. Due care is taken as to disinfection and disposal of the patients' discharges. Eating utensils and all other articles used in the sick room should be disinfected before removal, and the room should be well screened to exclude flies.

All suspected cases, especially those with gastro-intestinal symptoms, should be isolated and treated as positive cases until laboratory examination indicates the correct diagnosis. All contacts are segregated in small groups and stool examination instituted immediately for the purpose of detecting "carriers."

In the meantime, steps have been taken to destroy all sources of infection on board the vessel. The probabilities of infection on board can largely be determined from the history of the outbreak. If it has been of an "explosive" type, an infection of the water supply is suggested. This can readily be determined by a bacteriological examination of the water, considering the presence of *B. coli* as an indicator, or even testing for the cholera vibrio. If there be any scarcity of fresh water, a ship's supply should not be condemned unexamined. If there be ample fresh water available, the ship's supply can be disinfected by the addition of bleaching powder or permanganate of potash to the tanks, then pumping them out, after which a fresh supply of water is furnished. Or otherwise, the water supply can be purified by the addition of hypochlorite of lime.

If the voyage has consumed a number of days and there are only a few cases, the source of infection will generally be proved to be a carrier or carriers. The protected water supply and water carriage system of sewage disposal on modern vessels have materially altered the potentialities of cholera infection on ships. Formerly and before these sanitary conveniences were provided, the appearance of a case of cholera on a vessel was often followed by contamination of the water supply and most of the passengers and crew were sooner or later attacked if the voyage was a lengthy one.

As an added precaution for safety in carrying out preventive measures on a cholera-infected ship, fruits and vegetables that are generally not cooked before being eaten should be destroyed. The clothing and baggage of the sick and carriers should be disinfected, preferably by steam, but this is not necessary with respect to the ship's personnel in general. The bichlorid baths formerly in vogue are probably a waste of time.

Generally speaking, no treatment is demanded of the cargo as the holds remain sealed throughout the voyage and the chance of contamination is *nil*.

Fumigation or disinfection of the ship is not necessary except in compartments that have contained the sick or carriers, and thereby may have been contaminated. In this event, the floors and lower walls of such compartments should be washed down with a solution of carbolic acid or bichlorid of mercury, or other equally satisfactory disinfectant. This would be one of the few instances in which bactericidal measures are still called for in maritime quarantine procedure. The bedclothes, mattresses and other fabrics from the compartment where the sick have been should be steamed or soaked in a germicidal solution. Other than this no disinfection of the ship is called for.

The important element in the treatment of a cholera-infected ship (so-called "infected ship" although the ship itself usually is not infected at all, but merely the personnel) is the detection and isolation of cases and carriers with the safe disposal of their dejecta, until, by laboratory examination, they are proved to be free of cholera vibrio.

If the quarantine station be not provided with adequate laboratory facilities, in order to ascertain whether there are carriers, contacts will have to be detained for the period of incubation, i. e., five days. The detention of contacts for five days after the exposure to infection was formerly considered to be sufficient and will serve the purpose of excluding active cases of the disease. In more recent years, however, the important rôle played by carriers makes it essential that a bacteriological examination should be performed. See page 144.

#### SMALLPOX

Ordinarily those who have had smallpox or who have had a recent successful vaccination are not detained. All others must submit to vaccination. Persons declining vaccination are detained for the full period of 14 days before they are released. As a rule, it is not necessary to detain cabin passengers because there is smallpox in the steerage, or to detain the firemen because there is smallpox among the stewards. Vessels arriving with smallpox on board on which the cases have been properly isolated, personnel vaccinated, and other sufficient precautions

taken to prevent the spread of the disease, need not be quarantined further than the removal of the sick, the disinfection of compartments, baggage, and objects that have been exposed to the liability of infection.

### PLAGUE

In the management of a plague-infected vessel, a sharp distinction should be made between bubonic plague and pneumonic plague. From a quarantine standpoint, they are two separate diseases, one transmitted by insect bite, and the other by direct contact.

Pneumonic plague is a primary pneumonia, the epidemiologic factors of which appear to be more or less the same as in pneumococcus or influenza pneumonia. Bubonic plague is transmitted solely by insects, chiefly fleas, but possibly and on rare occasions by bedbugs.

Thus far, pneumonic plague has been largely confined to limited geographic areas, generally a northern climate—North Asia and the northern, higher regions of India. A few cases of pneumonic plague have recently (1919) occurred in California. This form of the disease has not been detected on any incoming vessel. Not infrequently there is a secondary pneumonia in cases of bubonic plague, but this condition is of no sanitary significance, and is distinctly different from the so-called pneumonic plague.

**Bubonic Plague.**—The treatment of a vessel infected with bubonic plague should be directed towards the destruction of all rats and fleas. Rats found dead or killed by fumigation should be immersed in coal oil and autopsied if possible, but in all cases the carcasses should finally be burned.

It is not necessary to detain passengers and crew who are in good health any longer than is incidental to the disinfection of the vessel.

Formerly, much stress was laid on the examination of passengers and crew, but there is no record of bubonic plague ever having been introduced into any port or place by infected man. It is only the infected rat or flea that carries the disease from one locality to another.

In handling an infected vessel it is first necessary to make sure that no rat may escape. Preferably, the ship remains at anchor in quarantine, or otherwise may tie up alongside the quarantine station wharf, with all mooring lines protected by metal discs three feet in diameter fixed at right angles to the hawser to which they are attached. The discs act as barriers to the passage of rats from ship to shore. After the passengers and crew are removed to the quarantine station, the vessel must be simultaneously fumigated in all parts to destroy rats and fleas. Hydrocyanic acid gas is the most efficient fumigating agency, but it is very dangerous and should be used only by those especially trained.

Sulphur dioxid is not very effective if the vessel be cargo laden, and

is at times very injurious to certain kinds of cargo, such as tea, silk, coffee, tobacco, etc., and to ship furnishings, and will often discolor paint, particularly white lead pigment. It is safe, however, and fairly effective when the compartment is empty and penetration and diffusion not so essential. Details of ship fumigation are described under separate heading on page 513.

Funnel gas (carbon monoxid) is not lethal to insect life, and, while satisfactory for ordinary rat destruction, it should not be employed for this purpose on plague-infected ships, as it will not kill fleas.

Rodent destruction on a cargo-laden vessel is best accomplished by repeated fumigations, the upper layers of cargo being discharged after each fumigation.

While it is ordinarily not necessary to disinfect the clothing and personal effects of passengers and crew, as fleas are seldom found on them, certain groups of persons require attention along this line. Lascars and other Asiatic crew men harbor fleas in the voluminous folds of linen or cotton (generally soiled) with which they swathe their bodies. The quarantine officer must necessarily exercise discretion as to the disinfection of the clothes and personal effects of passengers and crew.

Domestic animals, particularly cats and dogs, demand special attention on infected vessels. When there has been a great mortality among the rodent population, the dislodged fleas are very prone to secure temporary quarters on cats and dogs, and thus these pets, themselves immune to plague, may become a serious menace. These animals should be thoroughly immersed in a coal oil emulsion so as to kill all parasites.

**Pneumonic Plague.**—In the treatment of a vessel infected with pneumonic plague, the sick should be carefully isolated and passengers and crew segregated in small groups. Recovered cases should not be discharged until a bacteriological examination of the secretions of the nose and throat show absence of *B. pestis*, as cases may become carriers, at least for a short period of time. Contacts should be detained seven days before release. Special care should be exercised to detect new cases amongst the groups of contacts. Temperature should be taken twice daily, and any person developing the least rise of temperature should be immediately isolated and held under observation until the diagnosis is established.

Kitchen and dining room utensils used by the sick or convalescent should be thoroughly sterilized. On ship all living quarters should be disinfected and washed down with a solution of bichlorid of mercury or other germicide. Personal effects and bed clothes should be disinfected by steam.

With reference to measures for excluding plague infection, it is necessary to institute preventive measures, not only against vessels known to be infected, but it is also important that the same measures be carried

out against vessels arriving from ports known to be infected with rodent plague. Infection may have been introduced into the holds of the vessel and spread amongst the rats without any evidence of the disease being noted. Human cases on board a vessel would probably not appear unless there be infected rats in the superstructure. It is entirely possible for rodent infection to remain quiescent in the hold of a vessel, or for an undetected epizootic to prevail amongst the rats in the hold, even though the voyage may have consumed several weeks. Infected rats have been taken from the holds of vessels that have been out from an infected port for several weeks, notwithstanding which there were no human cases reported and no extensive epizootic amongst the rodents. See also page 331.

#### YELLOW FEVER

Vessels arriving at an infectible port from an infected port are fumigated and detained five days as a precautionary measure during the yellow fever season, even though there is no evidence of sickness on board. The yellow fever season usually extends from May 1 until October 1. The infectible ports are those situated upon the Atlantic seacoast south of the Chesapeake and those on the Gulf of Mexico.

Five days covers the period of incubation of most cases of yellow fever and is sufficient as a precautionary measure, but in special instances, as, for example, if a case of yellow fever has occurred on board the vessel, then the detention is six days following fumigation. The sick are isolated by the use of mosquito screens. Patients with yellow fever should not be moved if this involves exertion or excitement, which may aggravate the disease.

The vessel is fumigated with an insecticidal substance, preferably  $\text{SO}_2$ , or HCN, in order to kill the *Stegomyia calopus*. A search is made for breeding places, such as water casks, fire buckets, and other collections of fresh water where the *Stegomyia* larvae and pupae may develop. The disinfection of baggage and fomites is no longer practiced in the case of yellow fever. Experience has shown that wooden vessels are more apt to convey yellow fever than iron vessels. This is because wooden vessels carry water casks, which are the favorite breeding places for the mosquito, while iron vessels store their drinking water in tight compartments deep in the hold, inaccessible to mosquitoes. Vessels plying between infected and infectible ports should carry immune crews. See page 295.

#### TYPHUS FEVER

Typhus fever is one of the quarantinable diseases in which if one case appears on board a vessel there are apt to be several, especially if

the infection develops amongst the crew or steerage passengers, and hence all possible contacts should be detained in quarantine for the full period of incubation, which is 12 days.

If the disease has been confined to the steerage, there is no necessity for detaining cabin passengers, and vice versa. If the disease has appeared only in the crew quarters, and these are well separated from the passenger quarters, there is no occasion for the detention of the passengers.

First of all, the sick should be removed to the quarantine hospital and their clothing, personal effects and baggage thoroughly treated for the destruction of lice. The patient's body is treated with a delousing solution (mixture of kerosene and vinegar in equal parts, or kerosene and soft soap), and the application of some such solution is especially important for the destruction of head lice. The hair should be clipped not only on the head but also in the pubic and axillary regions, the clippings burned, and finally, the patient given a thorough bath.

Clothing is best disinfected by steam. Hydrocyanic acid is very effective for the destruction of lice, but is not a germicide.

All contacts should be passed through the baths, first being treated with a delousing solution, and their clothing and baggage should be disinfected.

Those detained should be segregated in small groups and temperatures taken twice daily, but if the delousing procedure has been efficiently performed, secondary cases are of no sanitary consequence. To be on the safe side, however, secondary cases should be isolated immediately upon their detection.

As to the treatment of the ship, no action is called for other than the assured destruction of lice in living quarters. The galleys, storerooms and holds need no treatment unless there be unusual circumstances that render them probably vermin-infested. Staterooms, crew quarters and steerage compartments should be fumigated with sulphur dioxide or hydrocyanic acid gas (technic as described on page 513), with bedclothes and furnishings remaining in place. After fumigation the vessel may be released with the personnel that have not been exposed—a new crew being furnished, if necessary.

The important feature in the treatment of typhus is that all vermin should be destroyed, cases detained, and contacts isolated until the period of incubation has elapsed. See page 370.

#### LEPROSY

An alien leper is not allowed to land. The law requires the vessel on which he arrives to take him back again. It is unconstitutional to forbid the landing of an American leper, but as soon as he lands he

comes under the laws of the city or state in which he finds himself. Alien lepers are detained at the quarantine station and placed aboard again when the vessel is outward bound.

**Quarantine Procedures.**—All vessels arriving at any port in the United States from a foreign port are considered to be in quarantine until they are given free pratique. The *pratique* is a certificate signed by the quarantine officer to the effect that the vessel and all on board are free from quarantinable disease, or the danger of conveying the same. In other words, free pratique is a permit issued by the quarantine officer which the master of the vessel must present to the collector of the port in order that his vessel may be admitted to entry.

Vessels in quarantine are required to fly a yellow flag (letter "Q" of the International Code) from the foremast. The quarantine officer boards the vessel usually upon the starboard side and examines the bill of health, the ship itself, the passengers, the crew, as well as the manifests of cargo, and sometimes the food and water supplies, etc. Vessels arriving after sundown must wait until sunrise for this inspection; the time and details, however, vary greatly and depend upon circumstances. Thus, at the port of Boston, there may be no more need to examine vessels bringing residents of London or Paris than there would be to examine a trainload of passengers from New York.

The detection of infection on board a vessel requires knowledge, tact, and sometimes a detective instinct on the part of the quarantine officer. Where one of the communicable diseases is suspected the temperature of every person on board should be taken. As a rule, all hands are mustered at a designated place on board the ship and then passed in review, one by one, before the examining physician; the number of persons are counted and compared with the ship's papers; each person is critically scrutinized for evidence of disease, and suspects are placed aside for more careful examination later. The clinical records of the ship's surgeon are inspected with special reference to the diagnosis of those who have received medical care during the voyage. The manifest of cargo is examined for second-hand goods, upholstered furniture, bedding, hides, hair, or other objects that may require disinfection. Finally, the ship itself is inspected, attention being given especially to the fore-castle, steerage quarters, the galley, etc.

**The Bill of Health.**—The United States Bill of Health is a document issued by our consul at the port of departure to the master of the vessel. The Bill of Health contains a complete description of the vessel, the number of officers, crew, and passengers (cabin and steerage), its sanitary history, and the sources and wholesomeness of water, food supply, etc. Finally, it contains a statement giving the number of cases and deaths from yellow fever, cholera, smallpox, typhus fever,

plague, and leprosy at the port of departure during the two weeks preceding the sailing of the vessel.

The American Bill of Health, which is a formidable document, must be obtained by the master of the vessel in duplicate, and presented to the quarantine officer at the vessel's port of destination. After these documents have served their purpose in affording to the quarantine officer the necessary information concerning quarantine inspection of the vessel, the bills of health are returned to the master of the vessel and by him surrendered to the Collector of Customs.

The Bill of Health is a consular document (State Department) at the port of departure, but becomes a customs' paper (Treasury Department) at the port of entry. Vessels arriving at any port in the United States or its dependencies from a foreign port without this official Bill of Health in duplicate are subject to a fine of \$5,000. Before the days of telegraphy the Bill of Health was an important document and often gave the quarantine officer the first information of pestilential disease abroad. The quarantine officer must now keep himself informed not only of the health conditions of the port of departure, but of the places from which the passengers and crew are recruited.

There are many kinds of bills of health; each country has a form of its own. Formerly a bill of health was simply a statement that the port of departure was or was not free of pestilential disease; that is, the bill of health was either "clean" or "foul." The American Bill of Health gives much more valuable information in detail. The only bill of health that is of service to the vessel upon arrival is the American Bill of Health, although several bills of health may be issued to the vessel at the port of departure. Thus, a British vessel leaving the port of Rio de Janeiro takes three bills of health, one from the British consul, required by the British admiralty laws, another from the Brazilian authorities, which is a clearance paper, and the third from the American consul, which is the only one of service upon reaching a port in the United States.

**The Equipment of a Quarantine Station.**—The equipment of a quarantine station consists of wharves, boarding vessels, such as tugs, launches, and rowboats; of an inspection place where passengers, crew, and suspects may be examined (the facilities on board the ship are usually inadequate for this purpose); of disinfecting apparatus for the use of steam, sulphur dioxid, formaldehyd, and insecticides; shower baths; detention barracks for steerage, intermediate, and cabin passengers, as well as the crew of the vessel; isolation wards in which cases of the quarantinable diseases may be cared for, and special wards where suspects or non-contagious cases may receive treatment. A well-equipped quarantine station further needs dining-rooms and kitchens for the various groups detained; quarters for the quarantine officers and help; a

wharf and boat house, and some provisions for recreation of those in quarantine to dispel the *ennui* of the isolation. Finally, a crematory, a steam laundry, and special arrangements for the disposal of sewage and garbage are important.

A laboratory is an essential feature of a modern quarantine station. It is necessary in order to make diagnoses and to recognize bacillus carriers, etc. In other words, a quarantine station, on account of its importance and isolation, must be a well-equipped and self-supporting community.

**Qualifications of the Quarantine Officer.**—A quarantine officer must necessarily be a good diagnostician. He should have an especial acquaintance with the diseases against which he stands monitor. The diagnosis of disease on an arriving vessel is doubly important, as it is in the nature of a medico-legal decision. Failure to recognize one of the quarantinable diseases jeopardizes the public health of the country, but, on the other hand, an error in diagnosis, even though in the interest of public health, may result in a needless loss of time and money. The quarantine officer, therefore, should be an experienced bacteriologist or should have such an expert as an assistant, since the accurate diagnosis of several of the quarantinable diseases is essentially a laboratory procedure, and even in those quarantinable diseases whose diagnosis yet rests on clinical evidence, laboratory procedure is important in establishing differential diagnosis. The quarantine officer must also be familiar with the modes of spread of the quarantinable diseases, and must know the value and limitations of the germicidal agents and insecticides he uses. Finally, he must be familiar with matters nautical and have an extensive knowledge of geography. It is the duty of the quarantine officer to keep posted as to the sanitary conditions of all countries, more especially towns and places having commerce with his port.

**Disinfection of Ships.**—The principles in the disinfection of a vessel do not differ materially from those of house and room disinfection. It should not, however, be attempted by one not familiar with the intricacies of marine architecture and matters nautical, for many special conditions are met with on board ship that are very different from those found on shore. While the principles of disinfecting as applied to a vessel present nothing unusual, the application of these principles calls for much ingenuity and the keenest vigilance on the part of the disinfector.

It is important to enlist the sympathies of those on board with the necessity of disinfection, for the successful accomplishment of the purification of the vessel may be materially helped by the cheerful coöperation of the passengers and crew; otherwise the difficulties of the problem are greatly magnified.

Formerly a distinction was made between the methods of disinfecting a wooden and an iron vessel. This arose from the fact that almost

all wooden vessels have some rotten and spongy wood, especially about the forefoot and bilge. There are also many more cracks and open joints about a wooden ship than a metal one which afford lodgment for organic matter. In addition to this, a wooden hull is always damper than an iron hull, for almost all wooden vessels leak more or less. It was formerly believed that the microorganisms of disease were apt to become deeply lodged in the moist dirt and organic matter of these crevices.

A vessel is rarely so badly infected that it needs a disinfection throughout. Just what portion of the vessel and its contents requires treatment is often a very difficult problem to solve. There is no more reason to fumigate the hold of a vessel because smallpox appeared in the cabin or steerage than there would be to disinfect the basement and sub-basement of a tenement house because a case appeared in one of the upper stories of the building. When a communicable disease occurs on board a vessel the infection may be confined to one or two compartments or to a limited area quite as successfully as this may be done in buildings on shore. "In case of doubt, disinfect," is not a bad rule for the quarantine officer to follow in his practical dealings with ships. Although the measures which must be taken are greatly in excess of the absolute requirements, yet discrimination is necessary, for the disinfection of ships for the quarantinable diseases has been greatly overdone. Vessels often need fumigation, seldom disinfection.

No routine method of disinfection can be prescribed for all infected ships. Discrimination must be exercised; disinfectants or fumigants must be selected that will destroy the virus and also the infecting agency involved.

It is, therefore, the duty of the quarantine officer to require a very thorough mechanical cleansing of all parts of the ship which, in his judgment, require it. This matter is dwelt upon because filth and vermin are conditions too frequently met with on the sea and one of great importance to communities and nations.

While the general methods of treating vessels are the same for most of the bacterial infections, special methods are called for with each disease. For example, in cholera particular attention must be paid to the water and food supply; for plague the destruction of rats and fleas is of prime importance; for yellow fever attention must be directed against the mosquito; for smallpox vaccination and the usual disinfection of the living apartments, clothing, bedding, and the like are required, while for typhus fever the warfare must be waged against lice.

Before the disinfection of a vessel is commenced it should be brought alongside the pier or barge containing the necessary apparatus. All the passengers are then to be taken off and all the crew, only excepting the few who are necessary for the safety of the vessel and those who are to help in the purification. The quartermaster, the boatswain, and

the carpenter are very useful hands to aid in the process on account of their practical knowledge of the individual peculiarities of the construction of the vessel and their faithfulness in carrying out directions with intelligence.

The disinfection of ships applies only to the living quarters of vessels infected with typhus, pneumonic plague, smallpox, leprosy or cholera, and then only to the particular part of the ship in which the sick have been. Steam sterilization of the ship furnishings, personal effects, clothing, etc., is not necessary in handling bubonic plague or yellow fever infected vessels.

When the personnel have left the vessel all their effects are removed and disinfected, if necessary, in accordance with the methods outlined for objects of that class. Disinfected baggage, bedding, and other objects, no matter what their character, should not be returned on board until the treatment of the vessel itself is finished. This injunction applies, of course, equally well to persons. In fact, no one should be allowed on the vessel except those actually engaged in the work, who, as far as practicable, should be immune and should wear suitable garments. All the bedding, bed clothing, hangings, floor runners, and other fabrics that have been exposed to infection must now be removed to the steam chamber. Especial care must be taken to obtain all the used and soiled linen, which is usually kept in special compartments called the "dirty linen lockers," which are usually under the care of one of the stewards. For some reason there is a dislike to disclose the presence of this soiled wash to the quarantine officer.

After all the objects needing disinfection by a special process have been removed, attention is then directed to the vessel itself. The various compartments of the vessel may be disinfected by any one of the methods described under Room Disinfection, formaldehyd being the choice of the gases and bichlorid of mercury (1-1,000) being the most suitable solution for the treatment of walls, floors, etc.

As to bichlorid disinfection, it may be stated that this procedure was formerly much employed at quarantine stations before the means of transmission of plague, typhus and yellow fever were known. One of the most important features of a quarantine station was the tank of bichlorid of mercury solution holding several thousand gallons of the mixture. It is a practice that has now well-nigh been abandoned, but still has a limited usefulness in washing down the floors and walls of compartments that have been contaminated by discharges from a cholera patient.

**Fumigation of Ships.**—In the purification of a ship, the greatest importance attaches to fumigation with sulphur or hydrocyanic acid gas. For many years sulphur dioxid was the agency chiefly relied on in the fumigation of vessels. Cyanid gas was regarded as too dangerous to hu-

man life, and in the strength assumed to be necessary, i. e., 10 ounces per thousand cubic feet of space, was also too expensive for routine employment. During the last four or five years, however, there has been much work done with this gas by officers of the Public Health Service, and while it can in no sense be considered a "fool-proof" gas in the hands of the inexperienced, the procedure has been so developed and improved as to make it reasonably safe when supervised by trained operatives.

Cyanid gas assuredly has many points of superiority over sulphur dioxide. Sulphur dioxide is not very diffusive, and when used on cargo-laden vessels has but little penetrating power, and thus the air pockets in articles of cargo or between packages of merchandise will often afford the rats a sufficient protection against the effects of the sulphur fumes. Sulphur dioxide is highly destructive to finer textiles, especially if damp; it tarnishes brass and gilt fixtures, damages delicately adjusted instruments, and causes discoloration of painted surfaces which contain lead pigments. The generation of sulphur fumes, if by furnace, requires expensive apparatus and, if by the "pot and pan" method, much labor and cumbersome apparatus. The pots and pans necessitate considerable time in placing and removing them and the exposure required is from 6 to 12 hours. Added to these defects, there is always the risk of fire from the burning sulphur. In contrasting sulphur fumigation and cyanid fumigation, the one feature in favor of sulphur is that it is not dangerous to human life.

On the other hand, cyanid gas is highly toxic to animal and insect life in the strength of 5 ounces of cyanid per thousand cubic feet of space, and this with rather short exposure. It is not injurious to the finest textiles nor to such articles as tea, coffee, tobacco, sugar, etc. It does not tarnish brass or gilt, nor discolor painted surfaces. It is easily and quickly generated and requires but simple equipment.

*Cyanid Fumigation of Ships.*—The method of preparation of the gas adopted by the Public Health Service is as follows: Paraphernalia required includes a tight wooden barrel (the well-made oak barrel used for kerosene serves excellently) for use in holds; earthen-ware crocks or jars for smaller compartments, and earthen-ware jugs as acid containers. The mixture of sulphuric acid and water is first prepared in the proportion of 2 fluid ounces of water to one and one-half ounces of commercial (66B) sulphuric acid. Finally, when most of the hatch coverings have been placed in position, sodium cyanid is lowered in a cheesecloth sack in the proportion of one ounce to each three and one-half ounces of the above mixture, dropped into the solution, bag and all; and the remaining hatch covers adjusted and battened down by a heavy tarpaulin.

The strength of the gas and the duration of exposure vary with

the objects sought. The Public Health Service standards in this respect are as follows:

For destruction of mosquitoes: One-half ounce of sodium cyanid per thousand cubic feet of space, exposure one-half hour.

For destruction of fleas: Two and one-half ounces sodium cyanid per thousand cubic feet of space, exposure one-half hour. N. B. This is of academic interest only, as in practice ships are not fumigated for flea destruction only, but always with the idea of rat destruction as well as flea destruction.

For destruction of rodents (rats and mice): Five ounces of sodium cyanid per thousand cubic feet of space, exposure for one and one-half hours.

For destruction of lice: Ten ounces of sodium cyanid per thousand cubic feet of space, exposure two hours.

For destruction of bedbugs: Five ounces of sodium cyanid per thousand cubic feet of space, exposure for one hour.

The above standards apply to empty holds and superstructures, except storerooms that have a large quantity of stores. In cargo-laden holds or in well-packed storerooms, the length of exposure is doubled.

If the potassium salt be used, a greater quantity is required. Three and three-fourths ounces of sodium cyanid is the equivalent of five ounces of potassium cyanid, and the latter when used is in the proportion of one ounce of potassium cyanid to one fluid ounce of sulphuric acid and two and one-half fluid ounces of water.

As a preliminary to cyanid fumigation the quarantine officer should make sure that no persons other than the fumigating force are on the vessel, and a certificate to this effect should be exacted of the master. This should further be confirmed by a search of the vessel by the quarantine officer himself or a trusted assistant. The compartments above the deck should have danger labels pasted on doorways after the fumigation has commenced.

The experience of the Public Health Service in fumigating several thousand vessels by cyanid as well as mammoth storehouses, makes it appear that there is no especial danger to the operator in the preparation of the gas.

The generation of gas is sufficiently delayed as to afford ample time for the fumigators to leave the compartment after dropping the cyanid into the acid solution; this, provided the compartments are above deck. The serious danger to human life arises incident to entering the compartment *after* the fumigation has been completed and the vessel opened up. To obviate this danger, powerful ventilating fans, driven by portable gasoline engines, are utilized at quarantine stations. They are lowered into the holds or placed within the doorways of above-deck compartments upon the completion of the fumigation.

The Public Health Service rules provide that no one may enter a compartment subsequent to cyanid fumigation until it has been pronounced safe by the quarantine officer. To determine this point, captive rats, cats, or guinea pigs are used as "indicators."

**Sulphur and Cyanid Contrasted.**—At one of the large quarantine stations on the Gulf, where some of the vessels were fumigated by sulphur and others by cyanid gas, a very thorough study was made as to the relative effectiveness of cyanid gas and sulphur dioxid when used on ships for rodent destruction. A very large force of trained trappers was available because of the anti-plague measures being carried out at the port, and, as the vessels generally stayed in port from one or two days to a week, ample opportunity was afforded for testing the effectiveness of the fumigation. Subsequent to fumigation, the vessels were flooded with traps. The observations extended over a period of one year and results recorded on several hundred ships. The number of traps placed varied from 20 to 140 per ship, according to the size of the vessel. Each ship after fumigation was carefully searched for dead rats and the number found recorded as to location. The number of days ships were trapped varied from one to ten, depending on the length of time vessels stayed in port.

By contrasting the number of rats killed by fumigation with the number subsequently trapped, a fairly reliable estimate was afforded as to the effectiveness of the fumigation. The results showed that cyanid fumigation destroyed 95 per cent. of all the rats on the vessel whether the holds were empty or loaded, and without regard to the location from which the rats were taken. In contrast to this result, sulphur fumigation killed only 77 per cent. of the rodent population on vessels under similar conditions. Studying the results according to the compartments fumigated, it was noted that in superstructures (including cabins, storerooms, poop deck and crew's quarters) cyanid fumes destroyed 94 per cent. of the rat population, whereas sulphur fumes, under similar conditions, destroyed only 55 per cent. of the rodent population. In cargo-laden holds, sulphur efficiency was 64 per cent. in contrast to 80 per cent. for cyanid fumes. In empty holds, the results of the two practices were more or less parallel; 99 per cent. efficiency for cyanid, and 96 per cent. efficiency for sulphur dioxid.

In this series of observations sulphur dioxid was used in the strength of 3 pounds of sulphur per 1,000 cubic feet of space, exposure of 6 hours, and the cyanid was used in the proportion of 5 ounces of cyanid per 1,000 cubic feet of space with exposure of 11¼ hours in holds, and 11½ hour for superstructures. Had the duration of exposure been doubled, the effectiveness of cyanid fumigation would probably have been perfect and the results of the sulphur dioxid fumigation would have been much better.

While cyanid fumigation is undoubtedly the preferred procedure where trained operators are available and the conditions favorable, sulphur dioxid has yet a wide field of usefulness, and on account of its safety in unskilled hands and the lack of operators experienced in cyanid fumigation, will doubtless continue to be the most commonly used agency for rodent and insect destruction on vessels.

*Sulphur Fumigation of Ships.*—The Public Health Service standard for sulphur dioxid as to strength and exposure is as follows:

For mosquito destruction: 2 pounds of sulphur per thousand cubic feet of space, exposure for one hour.

For destruction of lice: 4 pounds of sulphur per thousand cubic feet of space, exposure for six hours.

For destruction of rats and fleas: 3 pounds of sulphur per thousand cubic feet of space, exposure for six hours.

The above standard is for superstructures, partially filled storerooms, and empty holds. For cargo-laden holds and well-filled storerooms or in compartments that are packed with materials, the period of exposure should be doubled.

There are two methods in common use for generating sulphur dioxid for ship fumigation. The method more generally utilized is that known as the "pot and pan" method, but at a number of quarantine stations sulphur dioxid is generated by burning sulphur in a specially constructed furnace, the fumes being led into the holds through canvas funnels or hose. In the "pot and pan" method, ordinary Dutch ovens are used with a capacity of 10 to 20 pounds of sulphur. They are placed in pans of water in elevated positions on the 'tween decks or piles of ballast and distributed about the ship. To aid combustion, one-half gill of grain alcohol is added to each sulphur container. When all the pots are lighted, the hatches are battened down, the doors of the superstructures closed, and cracks closed by the use of paste paper. A pan of water is placed under each sulphur pot; this acts in part as a protection against fire, but it also serves the purpose of evolving moisture which is essential for the effectiveness of sulphur dioxid as a germicide.

For the purpose of computing the amount of sulphur or other gas to be used, a registered ton contains 100 cubic feet. A vessel of 5,000 net tonnage would therefore contain 500,000 cubic feet of air space in the cargo holds alone. Gross tonnage of a vessel indicates the actual cubic capacity; net tonnage, giving the cargo carrying capacity. The difference between the net tonnage and the gross tonnage indicates the space taken up by the engines and fireroom and the structures above deck. In sailing vessels and freighters, therefore, there is not such a great difference between the gross and the net tonnage as there is in large passenger vessels. In estimating freight-carrying capacity, 40 cubic feet of merchandise is considered a ton, but this unit should not

be confused with the registered tonnage, which is the basis for the measurement of the vessel.

**Special Precautions in Fumigating Ships.**—The various details in connection with fumigation of vessels are quite as important as the nature of the fumigant used, and the observance of these details to a large extent determines the effectiveness of the fumigation. All possible care should be observed by the quarantine officer to see that dead space in the vessel is opened up and all practical measures should be taken to aid in the diffusion of the fumigating gas; this is most essential when sulphur dioxid is used. All dunnage and loose material in the holds of a vessel that is not cargo-laden should be arranged in compact order and placed on elevated platforms to avoid rat harborage. If sulphur dioxid is generated in a furnace and led into the vessel it should be introduced at the lowest point and the hatches left open for a short while so as to permit the escape of air and hasten diffusion of the sulphur fumes. Pipe casing should be opened up and from one end of the vessel to the other there should be a certain number of limber boards removed so as to permit penetration of the gas into the bilges. Any planked-over space between the outer and the inner sheathing of a vessel should also be freely opened. In fact, wherever there is dead space it should be opened up so that there will be free circulation of the gas. Careful attention should be given to lifeboats, which are often infested by rats, which resort to those places for water. Preferably, lifeboats should be cleaned out and flooded by water prior to fumigation. Very close attention should be given to the poop deck, which is a space frequently containing a heterogeneous collection of litter and is generally badly rat-infested. As a rule, the engine room and fireroom do not harbor rats, but in the treatment of a plague-infected vessel they should be fumigated.

**Cargo.**—As a rule, the cargo of a vessel infected with pestilential disease needs no disinfection. Individual articles of the cargo, such as rags, household goods, second-hand articles, hides, wool, or food products, from infected localities may need treatment. New articles of merchandise or new manufactured goods seldom carry infection.

**Foreign Inspection Service.**—To aid the quarantine officer every American consul is required to report regularly certain facts concerning the presence and progress of epidemic diseases. Medical officers of the government are also stationed in various countries in order to supervise the sanitary condition of vessels, their cargo, and passengers leaving for the United States. This may be called preventive quarantine, for it is a distinct help in keeping out infection and facilitates trade and travel. Thus, in Italy, during the cholera times, an officer of the Public Health Service stationed at Naples successfully kept that disease off vessels sailing from Naples to the United States, whereas

vessels sailing from Naples to other ports and without sanitary supervision carried cholera in several instances.

**National versus State Quarantine.**—All the maritime quarantine stations in this country are now controlled by the National Government, excepting only the port of New York, where the quarantine function still remains under the jurisdiction of the State.<sup>15a</sup> The Federal quarantine service is administered by the U. S. Public Health Service, a Bureau of the Treasury Department.

It is evident that maritime quarantine should be administered uniformly so as not to prejudice or favor the commerce of a port. One of the objections to local control of quarantine is that there is frequent rotation in the position of quarantine officers due to local political changes. In addition to its other advantages, national control of quarantine insures the availability of a large corps of trained quarantine officers, whose experience in quarantinable diseases and in quarantine technic has been increased by duty in foreign countries and insular possessions where such diseases mainly prevail. Federal control of quarantine further permits of greater coöperation with other branches of the Federal Government such as the Immigration and the Customs Service. Furthermore, the Government is better able to observe the obligations of international sanitary treaties, and to demand reciprocal action on the part of foreign signatories of such treaties. Finally, as the object of quarantine is not only the protection of the local port, but the entire country, and since the benefits derived therefrom are not merely local in effect, the expense for the maintenance of quarantine stations should be borne by the country as a whole.

### *INTERSTATE QUARANTINE*

The regulations prepared under this act are more comprehensive with respect to quarantinable diseases than are the National Quarantine Regulations, since the former include not only the diseases enumerated in the maritime quarantine regulations, but also a number of communicable diseases, such as scarlet fever, typhoid, measles, whooping-cough, poliomyelitis, Rocky Mountain spotted fever, and epidemic cerebrospinal meningitis.<sup>16</sup> There is a distinct difference, however, between maritime quarantine and interstate quarantine. The provisions of the United States statutes with respect to the former give to the quarantine officer no latitude. Every ship entering from a foreign port must be inspected

<sup>15a</sup> Transferred to the Federal Government, March, 1921.

<sup>16</sup> This list has been extended by the Regulation of July 30, 1918, to include: Plague, cholera, typhoid fever, pulmonary tuberculosis, yellow fever, smallpox, leprosy, typhus fever, scarlet fever, diphtheria, measles, whooping cough, poliomyelitis, Rocky Mountain spotted or tick fever, anthrax and epidemic cerebrospinal meningitis.

and the quarantine officer must certify that they are free from quarantinable disease, whereas, with respect to interstate carriers or travel, quarantine laws and regulations are enforceable only to the extent that the Federal Government may provide proper agencies for such enforcement. A vessel from a foreign port may not enter a port of the United States except it be provided with a certificate of discharge from quarantine (free pratique), but a common carrier is not barred from interstate travel because of the lack of any such certificates. The interstate quarantine regulations impose numerous obligations on common carriers, and potential restrictions on interstate travel, but they have been actively enforced only under exceptional conditions. For obvious reasons, interstate travel is not subjected to the same rigid inspection as the personnel of vessels at seaboard quarantine stations.

It is evident, however, that interstate sanitary regulation is one of the important phases in which Government activity can accomplish especial good, for while the Government has limited authority within a state, it has practically unlimited authority so far as interstate relations are concerned. In the control of diseases by local authorities coöperation of the Government is essential since it is evident that if one state should rid itself of typhoid fever, measles or tuberculosis, it would speedily become reinfected from the neighboring states unless such reintroduction were prevented through the application of interstate quarantine restrictions. Interstate quarantine regulations, however, should be enforced with the same appreciation of relative values as applies to maritime quarantine. It would be indefensible to impose restrictions on commerce and on travel for the purpose of excluding measles or typhoid from a community which itself was doing nothing to diminish the prevalence of such diseases. On the other hand, if sanitary control of local conditions by state, county or city officials ever progresses to the extent that a community has rid itself of communicable diseases, it would have the assistance of the Federal Government in remaining clean.

By application of the provisions of interstate quarantine regulations, the National Government has wide powers in influencing local sanitary reforms. It can prevent the pollution of interstate streams, and by means of a proper standard for purity of water for interstate carriers, it can thus indirectly raise the standard of purity of local supplies. Furnished with adequate funds and facilities, Federal health authorities can exert a tremendous influence, through the enforcement of interstate sanitary regulations toward assisting local and state authorities in achieving sanitary reforms.

## SECTION IV

### IMMUNITY, HEREDITY, AND EUGENICS

#### CHAPTER I

#### IMMUNITY

**Infection and Immunity; Definition of Terms.**—Immunity or resistance to disease is the very foundation of preventive medicine. It is the overshadowing factor in hygiene. In this sense we use the term “hygiene” to include the care of the person, in contradistinction to “sanitation,” which deals with the environment. There is no sharp line of demarcation—we speak of hygiene of the teeth, of sleep, of bathing, of exercise, of food and drink, and of those conditions which are more or less intimately associated with the body. We speak of the sanitation of the home, of schools, of cities, of farms. Sanitary science considers the air, soil, climate, and our surroundings as they affect health. Sanitation, then, is largely impersonal; hygiene is personal, and, as far as the prevention of disease is concerned, one of the most important factors in hygiene is immunity.

The word “immunity” is a very old term—we still speak of immunity to crime,<sup>1</sup> but it is only of late years that we are beginning to understand the mechanism by which the body protects itself against infection. The advances have been so rapid that these studies may now be grouped into a separate science known as Immunology.

Immunity is a *function of all living beings* (animals and plants), and in its widest form is one of the fundamental properties of life. Thus, as long as we are alive the colon bacillus in our intestinal tract and the spores of the hay bacillus on our skin do us no harm, but the moment we die, and oftentimes shortly before death,<sup>2</sup> these and other bacteria invade our tissues and disintegrate them.

*Immunity* may be defined as the power which certain living organisms possess of resisting infections. Susceptibility is the contrary condition to immunity. *Hypersusceptibility* is a special state of an exaggerated power of reaction and is synonymous with *anaphylaxis*. *Allergie*

<sup>1</sup> We may speak of immunity “from” a disease, “to” a disease, and “against” a disease.

<sup>2</sup> Terminal infections.

is an altered process of reaction, often used as a synonym for anaphylaxis. The word *resistance* has practically the same signification as immunity. The term *tolerance* is commonly used to describe a limited form of immunity usually acquired by the repeated use of alkaloids, alcohol, and other poisons of comparatively simple chemical structure. While a high degree of tolerance may be acquired to such substances, a true immunity in the sense in which the term is now used is never produced. In the case of tolerance, antibodies are not found in the blood. For the most part true immunity is obtained against colloidal substances, while tolerance is largely limited to the crystalloids; this distinction, however, is not absolute.

There are all gradations and various kinds of immunity. It varies in *degree* from the weakest appreciable resistance to an absolute protection. It also varies greatly in *duration*—from the briefest period to a life span. Immunity, therefore, is a relative term. It may be *natural* or *acquired*, *active* or *passive*, *local* or *general*, *pure* or *mixed*, *specific* or *non-specific*, *family* or *racial*, *brief* or *lasting*, *strong* or *weak*, etc.

*Antigens* are all substances causing changes in the blood, which thereby acquires specific affinity for the antigen. All known proteins act as antigens when introduced into the body parenterally. Antigens, then, are substances capable of inducing the production of antibodies.

*Antibodies* are specific properties of the blood and other body fluids induced by antigens. They are not necessarily "bodies," but rather colloidal or physical states of the blood or other body fluids. Antibodies come down with the globulin fraction. Examples of antibodies are anti-toxin, agglutinin, precipitin, opsonin, lysin, etc. Antibodies are also called *immune bodies*.

A *parasite* is a plant or animal living in or with some other living organism (called its *host*), at whose expense it obtains food, shelter, or some other advantage. Parasitism is probably a form of specific adaptation. *Ectoparasites* or *external parasites* live upon the host, as fleas and lice. *Endoparasites* or *internal parasites* live in the body of the host, as intestinal worms, anthrax bacilli, malarial plasmodia, etc.

A *saprophyte* is a microscopic being that lives upon dead organic matter. Saprophytes and parasites belong to either the animal or plant kingdom; thus, the malarial plasmodium is an animal parasite, the meningococcus a plant parasite.

*Obligate saprophytes* are those which under no circumstances can be made to develop within the living tissues of a given animal. Diphtheria and tetanus bacilli come close to being strict or obligate saprophytes, for they usually develop and produce toxins on a localized area of dead tissue. Many parasites are *facultative*, in that while they thrive best in the living host, they may also be made to grow and develop upon dead organic matter.

*Symbiosis* is a form of parasitism in which two dissimilar organisms live together in more or less intimate association, to the advantage of one or both, and not harmful to either; while *antibiosis* is harmful to host or parasite, or both.

*Animal parasites* have feeble antigenic properties; that is, they have feeble or no power of stimulating the production of immune bodies. Animal parasites therefore lack the power of producing lasting or high grade immunity. For the most part, they produce a resistance that is effective only while the living parasites are in the host. One attack does not confer protection against subsequent attacks, as in syphilis, malaria, leishmaniasis, and most other infections due to animal parasites. On the other hand, many parasites belonging to the plant kingdom, such as certain bacteria, are particularly active in stimulating antibody production, and thereby produce a high grade and lasting immunity. There are exceptions to this general rule; thus, yellow fever produces a lasting immunity, whereas pneumonia does not.

The diseases in which one attack conveys a lasting immunity are plague, typhoid fever, cholera, smallpox, chickenpox, scarlet fever, measles, yellow fever, typhus fever and mumps.

The infections which do not confer lasting immunity are pyogenic cocci, gonorrhea, pneumonia, influenza, glanders, dengue fever, relapsing fever, erysipelas, malaria and tuberculosis.

An *infectious disease* is a reaction in the host caused by a parasite. It is the result of a struggle between two variable factors—the pathogenic powers of the parasite on the one hand, and the resistance of the host on the other, each of these again modified by variations in the conditions under which the struggle takes place. An infectious disease, then, is a reaction, not an entity.

*Septicemia*, or *bacteremia*, is a condition in which microorganisms become generalized and circulate in the blood. They may grow in the blood, but more often their presence in the circulating blood represents an overflow from a local focus or organ where they are growing. *Toxemia* refers to the general symptoms produced by the absorption of bacterial toxin. *Sapremia* is a febrile condition resulting from the absorption of putrefactive products (not microorganisms) caused by saprophytic bacteria.

A *pathogenic* microorganism is one that harms the host. There are all degrees of pathogenicity. A *non-pathogenic* parasite does not harm the host.

The *invasive power* is often spoken of as *virulence*, in contradistinction to *toxicity*. Toxicity implies merely the ability to produce poisons, and is not necessarily associated with the power to invade. Some organisms, like tubercle bacilli and the spirochetes of syphilis, have a very slow, gradual, but progressive power of invasion owing to the lack of

acute physiological reaction on the part of the host, resulting from the presence of the microorganisms. Microorganisms that possess active invasive powers produce general infections, which are often malignant, but may be benign.

*Communicability* means the facility with which parasites pass from one host to infect another. The degree of communicability varies enormously in different instances, and depends upon many variable factors, especially the mode of exit, the manner of transfer, the susceptibility, the channel of entrance, the dose necessary to cause infection, etc. There is no relation between communicability and virulence. Thus, smallpox, chickenpox, measles, epidemic influenza and common colds have a high degree of communicability; diphtheria and scarlet fever are much less active in this regard, while leprosy is spread with difficulty. We are ignorant of some of the factors concerned in the transmission of disease.

*Inheritance* plays an important rôle in immunity. Infection often takes a mild course among those races in which it has long been endemic, whereas the same disease suddenly introduced among a new people is relatively more severe and spreads more rapidly. Resistance as well as susceptibility may be transmitted from parent to offspring. In the case of natural immunity, the transmission is probably an instance of true inheritance, but in acquired immunity it is probably congenital. Compare Heredity and hereditary transmission of disease, page 607.

**Koch's laws or Koch's postulates** are now stated as follows: (1) A specific organism must always be associated with a disease, (2) when isolated in pure culture (3) and inoculated into a healthy susceptible animal it must always produce the disease and (4) should be obtained again in pure culture.

In Koch's first paper<sup>3</sup> on infectious bacteria, presented in 1878, he states that "the repeated findings of microorganisms in traumatic infections and experimental results connected with these findings would indicate that these diseases are of parasitic nature. This can only be proved, however, when it will be possible:

- (1) To find the parasitic organisms in every case of the disease.
- (2) To find them in such numbers and so distributed that all the symptoms can be ascribed to the parasite.
- (3) To identify morphologically a well characterized organism with each traumatic infection."

In 1885 Hueppe, a pupil of Koch, wrote a text-book of bacteriology<sup>4</sup> at Koch's suggestion. This book was written in the midst of the "spon-

<sup>3</sup>"Untersuchungen über die Aetiologie der Wundinfektionskrankheiten," Leipzig, 1878, by R. Koch. *Centralblatt f. d. med. Wissenschaften*.

<sup>4</sup>"The Methods of Bacteriological Investigation" (1885), by F. Hueppe, p. 11. Trans. by H. M. Biggs (1886), Appleton.

taneous generation" controversy which circumstance influenced the form in which Koch's postulates are given:

1. It is to be determined whether, in decomposition or disease, bacteria are present or not.
2. If bacteria are present it is to be determined what forms they possess.
3. Each form found to be present is to be cultivated by itself, free from all chemical and morphological mixtures—"pure cultures."
4. By transfers of really pure cultures to decomposable materials or susceptible animals, it is to be determined whether the bacteria found are the cause of the decomposition or disease.

It was not until 1890,<sup>5</sup> however, that Koch gave a clear statement of his fundamental concept of the relation of bacteria to disease. In discussing the view held by some at that time that bacteria only became pathogenic under the influence of the disease process he argued that:

1. If the parasite is found in every case of a disease and under conditions which conform with the pathological changes and clinical picture;
2. If it is not found in any other disease as an accidental and non-pathogenic parasite;
3. If after being completely isolated from the body and repeatedly transplanted in pure culture it can reproduce the disease on inoculation; then it cannot have an accidental relation to the disease, but the parasite must be the cause of the disease.

## MECHANISM OF IMMUNITY

The relation between seed and soil is often used to explain immunity, but this analogy does not help us very much for the reason that the soil does not react. A fertile soil may be considered susceptible; a barren soil immune. The seed in the first instance may be pathogenic or non-pathogenic. The host is able to resist the intrusion and growth of the non-pathogenic microorganisms and protect itself against harm through its mechanism of immunity. If the protecting devices are insufficient to guard against attack, the germs multiply, produce poisonous substances, or harm the host in other ways. The reason that the same microorganism may be pathogenic for one host and harmless for another depends upon the presence or lack of immunity. The virulence of a microorganism is an expression of the intensity of the reaction between the seed and the soil. Virulence may be strengthened or attenuated

<sup>5</sup> "Ueber Bakteriologische Forschung," by R. Koch. 1. Allgemeinen Sitzung des X Internationalen Medicinischen Congresses, am 4 August, 1890. (Berlin.)

either by increasing or decreasing the resistance of the host or by increasing or decreasing the resistance of the parasite.

**Theories of Immunity.**—It is now quite evident that the mechanism of immunity varies in different infections and, to a certain extent, even in the same infection under different conditions. We are still in ignorance of the mechanism by which the body protects itself against many diseased states.

Historically considered, immunology as a science dates back scarcely 30 years. Many primitive people attempted to immunize themselves in a crude sort of way, but with methods now recognized as essentially sound. Thus, South African tribes tried to protect themselves against snake bites by using a mixture of snake venom and gum; the Moors immunized cattle to pleural pneumonia by placing some of the virus under the skin of the animal. The inoculation against smallpox used from time immemorial, and vaccination with cowpox introduced by Jenner in 1798, are examples of the first practical use of specific methods in the history of immunity.

Pasteur was greatly influenced by Jenner's demonstration that a mild form of a disease protects against the severe form. Pasteur expanded the fact taught by Jenner into a general principle. Practically all of Pasteur's work in immunity that bore practical fruit, such as vaccinations against chicken cholera, anthrax, and rabies, is based upon this guiding principle.

Pasteur in 1888 expounded his "exhaustion" theory, which was the first attempt at a scientific explanation of immunity. Pasteur was a chemist and his theory was a simple chemical conception, largely based upon his work upon the fermentation of sugar with yeast. He regarded the body immune because its food supply was used up and the microörganisms could, therefore, no longer grow—just as yeasts cease to grow when the sugar is used up in a culture medium. It is now easy to disprove the exhaustion theory. Bacteria may continue to grow after recovery, as in bacillus carriers. Further, bacteria may grow well enough in the dead tissues and fluids of immune animals, and, again, immunity may be induced by the inoculation of dead bacterial products, substances which can hardly use up food material. Recently Pasteur's exhaustion theory has been revived in a modified form by Ehrlich, who considers that there is sufficient evidence of this form of immunity in certain cases, as in cancer. Ehrlich calls it "atreptic" immunity.

Chaveau proposed the "retention" theory, the exact opposite of the exhaustion theory. This theory is also based upon the analogy of the behavior of bacterial growth *in vitro* compared to their growth within the body. It soon became evident that bacterial growth ceases even though abundant food is present, and that this inhibition is due to the

retention of products of metabolism of bacterial activity. Chauveau considers that such substances are retained within the body, which thus protects itself against further growth and development of the microorganisms and thus establishes immunity.

The above theories are generalizations which have now little more than historical interest. We now know that no one mechanism of immunity will explain all cases. In some instances phagocytosis plays an important part; in others antibodies of various sorts; the side-chain theory appears to account for most of the facts in antitoxic immunity. In some cases the immunity is due to a negative property in that there is an absence of specific affinity between the toxin and the cells. In others it is a positive factor and is due to the presence of antibodies able to neutralize the toxic action. The mechanism of immunity in some instances resides mainly in the blood and fluids; in other cases it is evidently more directly associated with cellular activity. In some instances immunity depends upon the power of immediate reaction in the sense of anaphylaxis. In all cases the mechanism is probably complex and multiple.

The unsatisfactory state of our knowledge in certain fields of immunity is well illustrated in the case of anthrax. The mechanism of protection is not at all understood in this infection, which was the first and classic illustration of a germ disease. The mechanism of immunity in common colds is also complex and obscure.

Our resistance to disease is in many cases due to a simple mechanical or chemical protection against the invasion of the pathogenic microorganisms; that is, the tissues are susceptible enough, but are guarded against the invasion of the germs of disease. Many examples may be cited in this category. Thus, one of the important functions of the skin consists in this mechanical protection of the tissues underneath. There is but a single layer of epithelium between us and death. The smooth conjunctiva is protected by the constant washing of the tears and the motion of the eyelids. The lungs are safeguarded by the shape of the upper respiratory passages and the moisture of the mucous membranes, which act as a mechanical trap for many bacteria. Some of those that pass deeper are carried back by the mechanical action of the cilia. The sensitive and susceptible mucous membrane of the intestines is partly protected through the acidity of the gastric juice, which may be sufficient to destroy cholera vibrios and other microorganisms susceptible to acid.

**Cellular Immunity and Humoral Theory.**—Within the body the mechanism of immunity is an adaptation of cell nutrition. The mechanism varies with different infections and in different stages of the same infection. In certain diseases the immunity seems to reside mainly in the activity of the cells. In other diseases the immunity

is due chiefly to specific properties in the blood. The first is the *cellular* and the second the *humoral* theory. As we shall have occasion to see, the immune bodies in the blood are probably in all cases derived from the cells, so that the cells play the fundamental part in most processes of immunity. However, the great majority of the studies in immunology have been focused upon the changes in the blood. This is not due to the fact that the blood alone represents these changes, but that it best represents them, and thus affords the readiest method of attacking the problem.

The *blood* is the most fluid and most cosmopolitan of all the tissues of the body, visiting every part, bearing to each part certain substances, and removing from each part certain other substances. The blood is a digestive fluid, and in so far as immunity is concerned is even more important than the digestive fluids of the gastro-intestinal tract. The blood is not the usual handler of proteins. Blood ferments usually are not in an active state like trypsin or pepsin. The proteolytic enzyme in the blood, however, is of trypsin-like nature. There are, in addition, carbohydrates, lipases, etc., in the blood which doubtless play a very important rôle in immunity. There is at the same time an anti-ferment present which under normal conditions prevents autodigestion of the blood and tissues. It is evident that it is easy to study the blood and its changes, as some of it may readily and repeatedly be withdrawn during life in order to observe its changes without in any way harming the animal.

The fundamental processes of immunity within the body must all depend upon some *chemical or physical* change, but we know very little concerning the chemical composition of the substances that play the chief rôle or the physical nature of the changes. Great advances have been made in immunology despite this lack of chemical knowledge; for these advances we are indebted to experimental biology, through which we have learned the results of many effects without a knowledge of their nature or the intimate processes concerned.

**Natural Immunity.**—Natural immunity is an inherited character possessed in common by all individuals of a given species. It is inherent to a greater or less extent in all members of that species. It may be present at birth or develop in later years. There are very many examples of natural immunity. Thus, most of the communicable infections of man are peculiar to man; that is, the lower animals have a natural immunity to such diseases as measles, mumps, scarlet fever, typhoid fever, cholera, gonorrhea, syphilis, yellow fever, malaria, leprosy, and so on through a long repertoire.<sup>6</sup> Even tuberculosis, which is the

<sup>6</sup>It is true that some of these infections may be conveyed to monkeys or other animals by artificially introducing large amounts of the virus, but these animals do not contract these diseases naturally and therefore show a high degree of natural immunity.

most common and widespread of infections, has its own particular bacillus to which man is especially susceptible and to which the lower animals show a marked degree of natural immunity. On the other hand, man shows a high grade of natural immunity to a large number of infections to which the lower animals are subject, as rinderpest, black leg (symptomatic anthrax), Texas fever, hog cholera, etc.

The monopoly which man possesses of being susceptible to infections which the lower animals successfully resist is not confined to the bacteria alone, but includes many protozoa and higher animal parasites. Thus, the hookworm of man is different from the hookworm of the horse, the dog, the seal. Each host has its own species of hookworm which, though closely allied, are not interchangeable. That is, the horse has a natural immunity to the hookworm that is parasitic for man, and *vice versa*.

There is a group of infections, including the pyogenic cocci, anthrax, tetanus, malignant edema, glanders, actinomycosis, rabies, plague, foot-and-mouth disease, Malta fever, tuberculosis, milk sickness, infections with the paratyphoid bacillus, ringworm, and many higher forms of animal parasites, which are common to many species in widely different genera. Rabies is an example of an infection common to all mammalian species.

There are certain remarkable facts connected with natural immunity. For example, white mice are naturally immune to glanders, whereas the field mouse possesses a high degree of susceptibility. When we consider how slight must be the differences in the structure, the function, the chemistry, and the metabolism in the white mouse when compared with its gray cousin, we begin to appreciate the subtle differences and perhaps complex factors upon which immunity depends. If we could find out, for example, why the goat is resistant to tuberculosis while domestic cattle are particularly susceptible, we would have the foundation for a specific preventive and cure for that disease.

Practically all the individuals of a certain species have about an equal susceptibility or an equal immunity to a given infection. These factors are more constant than commonly supposed. Laboratory animals react with certainty and with striking uniformity to an infection of known virulence, provided the virus is brought into association with certain tissues. Thus, strikingly uniform results are obtained from a given culture of plague introduced subcutaneously into the guinea-pig, or of tuberculosis into the peritoneal cavity of the monkey, or of streptococci into the circulation of the rabbit, or of rabies under the dura of the dog, or of anthrax into the mouse. Pneumococcus and streptococcus cultures can be measured with reasonable accuracy upon white mice of approximately uniform weight. Man is no exception to this general statement, as far as may be judged from the data at hand. Practically

all persons are alike susceptible to smallpox, yellow fever, measles, tetanus, and many other infections. In epidemics some individuals escape. In other epidemics the disease varies greatly in severity. These apparent exceptions may not be due so much to varying degrees of immunity but rather to variation in the dose and virulence of the virus, the channel of infection, symbiosis, and other factors.

In some cases the immunity is so weak that the balance between health and disease is quite unstable. This appears to be the case with tuberculosis in man. We ordinarily possess sufficient natural immunity to tuberculosis successfully to resist small amounts of infection, but this resistance may readily be broken down by any influences which undermine our general vitality.

Natural immunity may be broken down by various means that weaken the animal, such as fasting, the production of an experimental diabetes with phlorizin, fatigue, excessive cooling of the body, as the clipping of the hair of thick-furred animals, etc. Thus, chickens are ordinarily naturally immune to anthrax, but may be infected if their feet are kept in cold water. White rats are resistant to anthrax, but become susceptible if the hair is clipped.

**Acquired Immunity.**—By acquired immunity is meant a specific resistance to an infection that is not naturally inherent in all the individuals of a species, but, as the term indicates, the immunity is acquired during the lifetime of the individual. Immunity may be acquired either through some “natural” event, such as an attack of a disease, or may be “artificially” induced by the introduction of some substance, such as a serum, toxin, vaccine, or a virus.

Acquired immunity may be either active or passive. *Active* immunity is induced by an attack of a disease or by the introduction of a virus or suitable toxin into the system. Immunity thus acquired is active in the sense that it depends upon a direct stimulation of the protecting mechanism resulting in a series of reactions within the body. *Passive* immunity, or transferred immunity, is mainly antitoxic immunity. Other antibodies also have the power of conferring passive protection, but in a lesser degree than antitoxins. Passive immunity is so called for the reason that the antibodies (antitoxin) are introduced into the body, which, therefore, takes no part in their formation. The injection of diphtheria toxin into the horse causes an active immunity in that animal; the injection of some of the antitoxin contained in the horse's serum into a child causes a passive immunity in the child. The protection against smallpox produced by vaccination is an example of active immunity; so also is the immunity produced by bacterial vaccines.

**Non-specific immunity** is an expression of natural immunity. The term is perhaps a misnomer—in any case, so-called “non-specific immunity” is slight and limited. It is stimulated by the parenteral injection

of a foreign protein, usually directly into the blood stream. The mechanism of non-specific immunity may include all the natural protecting mechanisms, such as phagocytosis, lysis, agglutination, and even anaphylaxis. The parenteral injection of a foreign protein influences chemical reactions, normal physiologic functions, and the integrity of tissues. It mobilizes the enzymes in the sense that they are made available for the reactions of immunity. Abderhalden holds that there is an increased amount of specific enzymes brought forth by the parenteral injection of non-specific proteins. Non-specific immunity brought about in this way finds its explanation in terms of anaphylaxis.

At best, "non-specific immunity" has very limited power and in only a few infections—notably gonococcic arthritis. The non-specific protein injected is usually typhoid vaccine or proteoses. The action of serum in pneumonia may also be an example of non-specific immunity. Just how it acts is not clear, but probably the changes in the physical character of the blood or the permeability of the membranes permits mobilization of the enzymes or other immunity principles where they can exert their beneficial effects. In other words, non-specific immunity is a term used to indicate the stirring up of forces inactive, but normally available for the defense of the body against infection.

**Mixed Immunity.**—Mixed immunity is a combination of the active and passive. This is used practically in plague prophylaxis and has been proposed for other infections. It consists in injecting a mixture of antitoxic serum and the appropriate bacterial vaccine. The advantage of this procedure consists in the fact that the passive or antitoxic immunity diminishes the severe reactions which sometimes follow the introduction of a bacterial vaccine. It also affords an immediate protection and thereby guards the body during the time it always takes for the active immunity to become effective.

The toxin-antitoxin mixture used against diphtheria is an example of mixed immunity. In this case only enough antitoxin is used to guard the toxin.

In the mixtures known as sensitized vaccines, the action is bacteriolytic rather than antitoxic.

**How Active Immunity May Be Acquired.**—Immunity may be acquired by:

- (a) An attack of a disease.
- (b) By the introduction of a virus.
- (c) By the introduction of a vaccine.
- (d) By the introduction of a toxin, or other product of bacterial activity.

(a) *An Attack of the Disease.*—Certain diseases, whether acquired naturally or induced artificially, leave an immunity which varies greatly

in degree and duration. The following diseases leave a definite immunity of high, though variable, grade: smallpox, yellow fever, measles, whooping-cough, scarlet fever, cerebrospinal meningitis, infantile paralysis, typhoid fever, typhus fever, chickenpox, mumps. Second attacks of smallpox, measles, typhoid fever, and other infections in this list are not uncommon, showing that the immunity is rarely if ever absolute.

Some diseases, such as pneumonia, erysipelas, and malaria, seem to predispose to subsequent attacks, that is, diminish resistance. Even in this class of infections there must be a certain amount of immunity, however short, else the patient would not recover.

(b) *By the Introduction of a Virus into the System.*—The practice of intentionally inoculating smallpox was the first example in preventive medicine in which use was made of the fact that one attack of a disease confers immunity to a subsequent attack of the same disease. The present-day vaccination with cowpox (a modified smallpox) may be considered as belonging to this category. The principle is used to a much greater extent in veterinary practice either by using a small amount of the virus, or by introducing it in an unusual way or by inoculating the animals at a time when they are found to be least susceptible. In this way a benign form of the disease is produced which protects against the severe and fatal forms. These methods are used in Texas fever, rinderpest, pleuropneumonia, anthrax, etc.

A distinction is made between a virus and a vaccine. If the material used contains the living active principle it should be called a virus. If the virus is dead it should be called a vaccine.<sup>7</sup>

The highest and most lasting degrees of immunity may be produced by the introduction of the living active principle into the system, thus imitating nature. The virus may be diminished in virulence as in anthrax, vaccinia, or rabies. A high grade of immunity to plague and cholera may be induced in man by the injection of living cultures. In the case of plague the cultures must be greatly diminished in virulence.

In the case of cholera virulent strains may be used, as this disease is neither a bacteremia nor septicemia, and there is very much less danger in introducing the cholera vibrios into the subcutaneous tissue than in taking them by the mouth. This principle of introducing the virus into a resistant tissue can be taken advantage of in various infections, provided the virulence of the disease depends largely upon the channel of infection. The virulence of the virus may also be diminished by certain definite processes, such as growing the culture at an unusually high temperature, as in the case of anthrax; or by prolonged artificial cultivation, as in the classic instance of chicken cholera; or by drying, as in rabies; or by passage through animals, as in smallpox (cowpox);

<sup>7</sup> Vaccine (*vacca*, a cow) is not a good term, but is now too deeply rooted to change.

or by growing on unfavorable media; by the use of very small amounts of the virus, as in tuberculosis and many other infections; or by the use of closely related strains, such as the human tubercle bacillus for bovine immunization. Repeated injections of a virus induce a much higher and more lasting immunity than single inoculations.

(c) *By the Introduction of a Bacterial Vaccine.*—The immunity produced by the introduction of a vaccine into the body corresponds precisely to the immunity acquired by the introduction of a virus, the only difference being that the living virus produces a more lasting and higher degree of protection than that produced by the dead vaccine. The advantages of using a vaccine instead of a virus are obvious.

### BACTERIAL VACCINES

Dead bacteria, when injected into the tissues, usually produce a local reaction at the site of inoculation and also a general reaction. The local reaction consists of swelling, pain, redness, and other indications of irritation and inflammation. The general reaction consists of fever, headache, pains in the muscles, especially in the back and legs, malaise, and sometimes nausea. The reactions usually come on within a few hours after the vaccine has been introduced and rarely last longer than 24 to 48 hours. It is customary to give the vaccines in the afternoon, for then most of the symptoms have passed by the next morning.

The vaccine is usually prepared from a fresh twenty-four-hour growth of a pure culture of the microörganism upon the surface of agar. In this way secondary metabolic products in the medium are avoided by simply removing the surface growth. When liquid cultures are used the foreign substances contained in the medium may complicate the reactions. The cultures are usually killed by exposure to heat at from 53° to 60° C. for one hour. High heat, while certain to kill the virus, is undesirable, for the reason that it coagulates the albuminous substances in the bacterial cell and otherwise alters the chemical structure of the microörganism. The closer the vaccine approaches the virus the better the results, so far as immunity is concerned. Therefore, many investigators prefer to kill the microörganisms with carbolic acid, chloroform, or some other suitable germicide.

Preventive inoculations with bacterial vaccines are now much practiced in the case of typhoid fever, plague, and cholera, and are destined to be extended to other infections. The dose and details have been discussed under each disease. The important domain of vaccines is protective, not curative.

*Sensitized vaccines* are made by mixing the bacteria with its specific antibody and then washing away the excess of antibody. If, for example, typhoid bacilli are injected into a rabbit, antibodies appear in the blood

serum of the rabbit. If new typhoid bacilli are mixed with this rabbit serum (which must be first inactivated by heating to 56° C. to destroy complement), the bacilli become sensitized. In other words, the bacteria unite with the specific antibodies present in the rabbit's serum. Sensitized bacilli may be used dead or alive.

The advantages of sensitized vaccines have been advocated by Besredka, Calmette, Salembini, Gay and others. It is claimed that the protection comes quicker, but it is not always as high or as durable.

*Polyvalent vaccines* consist of several cultures mixed and given at the same time. Thus, a tetravaccine,<sup>8</sup> containing typhoid, paratyphoid A and B, and cholera, was used in Serbia.

The injections are always given subcutaneously. Usually three or four injections are given at intervals of about five to ten days. Several injections produce an immunity of much higher grade and longer duration. In most instances the acquired immunity lasts from two to five years, and may be renewed.

*Lipovaccines* consist of emulsions of the bacteria in a bland neutral oil. The advantages claimed for lipovaccines are that they diminish local reaction, because absorption is retarded; that a very large amount can be given in one dose without toxicity; that a focus of antigen is established which acts continuously. The oils are supposed to have a detoxicating action. All these theoretical advantages have not worked out in practice; in fact, lipovaccines give only about half the protection of saline emulsions.

**Standardization of Bacterial Vaccines.**—Bacterial vaccine may be standardized by several methods:<sup>9</sup> Wright's method<sup>10</sup> consists in comparing the number of bacteria with the number of red corpuscles on a stained slide. The errors in this method are numerous and may vary from 50 per cent. to 100 per cent. if counted on the same film by different observers.

The nephelometer method described by McFarland<sup>11</sup> consists in comparing the opacity of the culture with a series of standardized tubes containing a fine precipitate. This method is a guess, for the errors vary from 25 per cent. to 200 per cent. Dunham<sup>12</sup> obtains reasonably accurate results with the Kober nephelometer. This method only takes 10 minutes and is practical.

Wilson and Dickson proceed by weighing the dried culture on a piece of thin platinum foil. The method has not been used on account of the special apparatus necessary for its application.

<sup>12</sup> *Journ. Immunology*, Vol. V, No. 4, July, 1920, p. 337.

The plate-culture method consists of standardizing the suspension by counting the colonies which develop. The defects are that it requires two or three days before the results can be known; that the colonies may represent the growth of more than one bacterium; and some of the bacteria may not grow. The plate method always gives low counts varying from 25 per cent. to 150 per cent. less than the hemocytometer.

The gravimetric method employed by Hopkins<sup>13</sup> consists in the use of a special centrifuge tube, the end of which is drawn out into a small tip. This is graduated in hundredths of a cubic centimeter. The amount of centrifugalized sediment may be read directly upon the scale. The method gives but approximate results.

Mallory and Wright<sup>14</sup> first used the hemocytometer for counting the number of bacteria in a suspension. The chamber used is made for counting blood plates by the Helbar method. A method which actually counts the number of bacteria, offers the most accurate technic for standardizing vaccines.

**Specificity.**—Most of the reactions in immunology are specific—not absolutely so, but relatively; that is, antibodies, such as agglutinins, lysins, precipitins, or opsonins, usually act upon the corresponding antigen with much greater vigor than upon any other. An immunity to one disease, no matter how produced, whether natural or acquired, affords no protection against other diseases. There is, however, no absolute specificity, just as there is no absolute immunity.

Certain microorganisms and their toxic products show a remarkable predilection for certain cells or tissues. In this sense a microparasite or a toxin may be as specific in its action as a qualitative chemical reaction. Thus, there is a specific relation between tetanus toxin and nervous matter, while the poison has little or no affinity for other tissues. The poison of infantile paralysis picks out certain cells in the central nervous system upon which it acts specifically. Also in rabies the brunt of the lesions falls upon the cells of the central nervous system. The toxic products of the *Bacillus botulinus* is also a specific nerve poison, and at least one of the poisons in diphtheria toxin (toxogen) acts specifically upon the nerves. The toxic substances may also react upon less important or indifferent tissues, but such action is often masked. The specific action of toxins explains in part the local immunity enjoyed by some tissues and further explains why certain viruses are comparatively harmless when introduced into the body through unaccustomed channels. We have already seen an example of this in a case of cholera when introduced into the subcutaneous tissue. In this case the subcutaneous tissue is resistant to the invasion of the

<sup>13</sup> Hopkins, J. G.: "A Method for Standardizing Bacterial Vaccines," *J. A. M. A.*, May 24, 1913, p. 1615.

<sup>14</sup> Mallory and Wright: "Pathological Technic," Ed. 4, Philadelphia, W. B. Saunders Company, 1910.

cholera vibrio, and these microörganisms cannot find their way to the intestinal tract. The case of smallpox is instructive, for this is an infection for which the epithelial structures have a specific susceptibility. It is practically impossible to infect a susceptible animal with cowpox when the virus is introduced subcutaneously or directly into the circulation. The same is probably true of smallpox. When smallpox virus is introduced by inoculation upon the skin the disease is much milder than when the virus is introduced naturally by way of the respiratory tract. Evidently the skin offers greater resistance to the smallpox virus than is offered by the mucous membranes. On the other hand, foot-and-mouth disease cannot be given to man or the cow when rubbed upon the skin, although these animals are very susceptible when this virus is introduced into the general circulation or rubbed upon the mucous membrane of the mouth. Every worker in a bacteriological laboratory is familiar with the difference in susceptibility of different tissues and knows the importance in experimental work of bringing the virus in association with appropriate structures.

Certain microörganisms, such as *B. tuberculosis*, pus cocci, the pneumococcus, etc., have the power of affecting almost every tissue and organ of the body. No part of the body is immune to the tubercle bacillus, but even in this infection some tissues are more susceptible than others. Thus, tuberculosis of the muscle is extremely rare; the lungs and lymph nodes are especially vulnerable.

The stomach is comparatively rarely attacked by infective processes, although constantly exposed. The vaginal mucous membrane in the adult and the bladder are resistant to gonorrheal inflammations. There are many similar instances of specific resistance of tissues.

The specific action of toxins gives us a ready reason why certain species of animals are immune to certain infections. In this case the immunity is not the result of any special or specific reaction, nor is it the result of any positive character possessed or acquired by the body, but is a negative trait entirely, due to the absence of specific chemical affinity between the cells and the toxin. The turtle is immune to tetanus because there is no combining affinity between the nerve cells of the turtle and tetanus toxin. The immunity, therefore, depends upon the absence of the appropriate cell receptors. Rats are highly immune to diphtheria toxin and hogs to snake venom. In these cases antitoxin cannot be demonstrated in the blood of the rat or the hog, and, so far as can be determined, when the toxin is injected into these animals it is not neutralized in the body. The simplest conception of the mechanism of immunity in these cases is to regard it as depending upon a negative factor resulting upon the absence of suitable receptors in the sense of Ehrlich's side-chain theory.

**Local and General Immunity.**—Local and general immunity depends upon this variation in susceptibility of the different tissues to different infections. It is doubtful if there is a true general immunity in any case, for a general immunity is in almost all instances based upon a local resistance. Even antitoxic immunity in diphtheria, due to the antibodies in the general circulating blood, is the result of a localized neutralization in which many of the organs and tissues of the body take no part. There are many examples of local immunity. *Trichinella spiralis* affects especially the striped muscles and never the bones. Diphtheria seldom extends down the esophagus. The most marked example, perhaps, is the almost perfect local immunity of the scalp to ringworm in adults, which contrasts so markedly with the absolute susceptibility of children, whereas the susceptibility of the skin of the body to the same parasite is, if anything, greater in adults than in children (Emery).

Many remarkable instances of local immunity are shown by the tissues and must be familiar to all. Thus, erysipelas does not, as a rule, extend into the subcutaneous tissues, although the streptococcus may be there; rarely does it extend back into the area of the skin recently affected.

The immunity of a part is increased or diminished by the presence or absence of an adequate blood supply. As a rule, very vascular structures enjoy a comparative immunity to infections which frequently attack other tissues relatively poor in blood supply. It may be stated as a general rule that the more copious the supply of healthy circulating blood the greater the resistance to infection, and *vice versa*. This largely accounts for the local immunity enjoyed by the mucous membrane of the mouth and lips, which are constantly exposed to wound infections. Herein we also have an explanation of the utility of fomentations and other hot applications in the initial stages of an infective lesion. The same explanation is applied in Bier's method of passive congestion, in which an excess of blood is made to flush the tissues. The local immunity of the part may be diminished by a local anemia from any cause, by the presence of dead or injured tissue, by the action of irritants, trauma, etc.

Metchnikoff has pointed out that in many infections general reaction is in inverse ratio to the local reaction at the site of introduction of the virus. A severe and prompt local inflammatory reaction indicates an active power of protection. The increased volume of blood, the cells, the fluids of the blood and tissues are concentrated about the invading bacteria to wall them off and destroy them, that is the immunity of the body against a general infection frequently depends upon the promptness and the activity of the local power of reaction.

Some infections, notably streptococci, plague, or organisms belonging to the hemorrhagic-septicemic group, may invade the body with

little or no local inflammatory reaction; that is, little or no barrier is set up against these microorganisms: they may invade the blood and tissues without resistance and thus cause fatal septicemias.

**Bacillus Carriers.**—Upon recovery from an infectious process the body usually rids itself completely of the infecting agent. In other words, the immunity which follows an attack of an infectious disease is usually associated with a power the body has of disinfecting itself. In most cases the patient is convalescent or completely restored to health before the cause of the disease has disappeared from the tissues. This bespeaks a vigorous protecting mechanism, but when this resistance is lowered for any reason a relapse may ensue.

In many instances recovery takes place, but the living virulent microorganisms continue to live in the body. This constitutes "immunity without sterilization," a term introduced by Ehrlich, though a more precise expression would be "immunity without disinfection." Such persons are now known as "carriers." The immunity protects the carrier but endangers his fellowmen. Bacillus carrying is common in diphtheria, typhoid fever, cholera, pneumonia, epidemic cerebrospinal fever, influenza, and many other bacterial infections. Protozoön carriers are also a common phenomenon. The best examples are found in malaria, trypanosomiasis, Texas fever in cattle, etc. Analogous instances are also found in the higher parasitic worms in which the individual who carries the parasite is not affected. Thus, the negro and the Filipino show a relatively high degree of immunity to the hookworm and thus endanger their more susceptible white companion. Lower animals, including insects, may also be carriers.

*Convalescent carriers* are those that continue to harbor the microorganisms during recovery; this is usually a matter of 8 to 10 weeks or less.

*Passive carriers* are those who harbor the microorganisms without having had the disease.

*Active carriers* are those who continue to harbor the microorganisms after an attack of the disease.

*Acute, transitory or temporary carriers* harbor the microorganisms for brief periods of time; *chronic or permanent carriers* for months and years. Both passive and active carriers may be either temporary or permanent.

*Intermittent carriers* shed the microorganisms from time to time.

Carriers further divide themselves into three groups: (1) *intestinal and urinary carriers*, as typhoid, cholera, dysentery, etc.; (2) *oral carriers*, as diphtheria, pneumonia, etc.; (3) *blood and tissue carriers*, as malaria.

Bacillus carriers play an important rôle in spreading infections. They explain many mysterious facts in the epidemiology of diphtheria,

typhoid fever, cholera, cerebrospinal fever, malaria, etc. The bacillus carrier is sometimes a danger to himself. This is seen in pneumonia, influenza, streptococcal and other infections.

While it is undoubtedly true that bacillus carriers play a very important rôle in spreading infection from man to man, the relative importance compared with other modes of transmission cannot be stated in percentage. The subject is still too young for definite quantitative figures. There is no doubt that bacillus carriers are more important in some diseases than others and play a variable rôle under different circumstances in the same disease. In our studies of typhoid fever in Washington one carrier was discovered in the examination of 986 healthy individuals. This would mean approximately 300 typhoid bacillus carriers in the District of Columbia. If this proportion is correct, it would account for the endemicity of typhoid fever in Washington. Perhaps the residual typhoid fever in many places is largely kept alive through bacillus carrying. Great sanitary reforms, such as the change from polluted to pure water, causes both a decline in the amount of the fever and a decrease in the number of carriers. It now seems evident that polluted water and infected milk will not always cause the disease directly in the persons drinking these fluids, but may produce carriers who either contract the disease themselves subsequently or give it to others by passing the virus on in a more concentrated and virulent form, or to more susceptible individuals.

It is evident from the nature of the case that the cure and control of bacillus carriers is one of the vital problems in preventive medicine. It is not only largely through them that infection is spread, but the infections themselves are kept alive in these carriers, who bridge over the interval between outbreaks. It is quite conceivable that with our modern methods of isolation and disinfection certain diseases could readily be rendered extinct were it not for carriers.

Immunity is, therefore, a double-edged sword, in that it protects the carrier but endangers his neighbor. The control of bacillus carriers is a difficult problem. Such unfortunate persons cannot always be imprisoned, nor is strict isolation always necessary. It is sufficient in the case of typhoid fever to restrict the activity of the carrier. Thus, a typhoid carrier should not cook, prepare, or handle food, or have anything to do with the production or distribution of milk. We have no satisfactory cure for carriers—this is a problem for the future; but their number may be lessened—this is a problem for the present.

It should always be remembered that the number of carriers will diminish proportionately with the number of cases of certain infections and that every improvement in the water supply, the milk supply, the food supply, and our sanitary conditions generally will have a tendency sharply to diminish the number of carriers, especially of intestinal infec-

tions. Therefore, while isolation, disinfection, and other methods used to control the spread of infection will never be completely successful as long as the carrier is omitted, nevertheless, these methods are entirely justified even though only partially useful. It is the duty of public health officers to check the spread of infection wherever it may be found. In time ready methods of recognizing bacillus carriers and means of neutralizing their potential danger will be more effective than is now possible.

**Latency** is closely allied to bacillus carrying. The malarial parasite may remain latent in the spleen and other internal organs for years, during which time the person remains in good health. But when the resistance is reduced by exposure, fatigue, starvation, or other depressing influences the disease again breaks out. The gonococcus may also remain latent for years. I am familiar with one instance in which the tubercle bacillus remained latent in the axillary glands for 10 years and then became active owing to a condition of depressed vitality. Typhoid osteitis may develop years after an attack of typhoid fever, and we can only assume that the bacilli have remained latent in the tissues all that time. The phenomenon of latency also occurs in rabies, tetanus, and other infections.

**Lowered Resistance.**—The factors which lower our general resistance to disease are many and varied. The condition known as depressed vitality, lowered tone, general debility, weakened constitution, and terms of similar import imply a condition in which immunity is lowered in a general sense. The principal causes which diminish resistance to infection are: wet and cold, fatigue, insufficient or unsuitable food, vitiated atmosphere, insufficient sleep and rest, worry, and excesses of all kinds. The mechanism by which these varying conditions lower our immunity must receive our attention, for they are of the greatest importance in preventive medicine. It is a matter of common observation that exposure to wet and cold or sudden changes of temperature, overwork, worry, stale air, poor food, etc., make us more liable to contract certain diseases. The tuberculosis propaganda that has been spread broadcast with such energy and good effect has taught the value of fresh air and sunshine, good food, and rest in increasing our resistance to this infection.

There is, however, a wrong impression abroad that, because a lowering of the general vitality favors certain diseases, such as tuberculosis, common colds, pneumonia, septic and other infections, it plays a similar rôle in all the communicable diseases. Many infections, such as smallpox, measles, yellow fever, tetanus, whooping-cough, typhoid fever, cholera, plague, scarlet fever, and other diseases, have no particular relation whatever to bodily vigor. These diseases often strike down the young and vigorous in the prime of life. The most robust will succumb quickly

to tuberculosis if he receives a sufficient dose of the virulent microörganisms. A good physical condition does not always temper the virulence of the disease; on the contrary, many infections run a particularly severe course in strong and healthy subjects, and, contrariwise, may be mild and benign in the feeble. Physical weakness, therefore, is not necessarily synonymous with increased susceptibility to all infections, although true for a few of them. In other words, "general debility" lowers resistance in a special, rather than in a general, sense.

The mechanism by which the various causes that lower vitality and increase susceptibility act is in most cases quite obscure. Here is a field for laboratory research in immunology that offers rich reward of immeasurable practical good. Some of the factors concerned will be briefly discussed.

*Exposure to wet and cold*, especially in combination, is a frequent source of lowered resistance. The exact way in which such exposure acts is not definitely known, but laboratory researches offer material for a number of suggestions. Emery<sup>15</sup> sums up our knowledge upon this subject as follows:

"Immunity is to a very large extent a function of the leukocytes, which are specialized cells to which the defense of the body is entrusted. Now, the functions (movement and phagocytosis) which can be easily investigated are found to be dependent in a very high degree on temperature, acting best at the temperature of the body, or slightly above; and it is highly probable that the more subtle functions of the leukocytes may be similarly depressed by a low temperature. The exposure of the skin to cold, especially if the animal heat be abstracted more quickly by evaporation of moisture on the surface, will lead to a cooling of the blood which circulates through it, and hence to a slight, though appreciable, cooling of the whole blood. This, it is true, is soon compensated for, and no great amount of cooling of the whole body occurs; but, even so, it is quite possible that the periodical chilling of the leukocytes during their repeated passages through the cold skin may be sufficient to diminish greatly their functional activity, and to lower the resistance to a point at which infection may occur, and when once pathogenic bacteria have gained a foothold the resistance will for a time tend to decrease. There is also some evidence going to show that exposure to cold may lessen the production of the defensive substances which occur in the blood (alexin, antibodies, etc.), though this is not fully proved. It is worthy of note that the loss of immunity due to the action of cold and wet on one part of the body (such as the feet) is a *general* one, and may result in a nasal catarrh, an attack of pneumonia, acute rheumatism, etc., according to the nature of the infection at hand. It is not necessarily a local infection of the chilled

<sup>15</sup> "Immunity and Specific Therapy," 1909, p. 9.

region. This is very well shown experimentally. Fowls are immune to anthrax, but are rendered susceptible if they are kept for some time standing in cold water; and this acquired susceptibility is then a general one, and not merely of the feet.

"Cold and wet, as is well known, have less action when accompanied by energetic muscular exercise, so long as this does not reach the extent of undue fatigue. This is not because less heat is lost during exercise. The reverse is the case. The suggested explanation is that the muscular metabolism leads to an increased production of heat, and at the same time the cutaneous capillaries are dilated and the heart accelerated, or that the circulation of blood through the skin occurs quickly; further, the internal temperature of the body may actually be raised several degrees. The result is that the temperature of any given leukocyte never falls much below normal, if at all, since it comes from the internal regions where the temperature is raised, passes rapidly through the skin, and returns again to the interior of the body."

Trench foot is a good example of lowered resistance due to the local effects of cold and wet, combined with muscular inaction.

The effect of *fatigue*, either alone or in conjunction with cold and wet, is also well known, and is one reason for the excessive mortality from disease of armies in the field. Cerebrospinal fever is a good instance of the effect of fatigue and exposure. The war has again taught the lesson that to make the soldier too rapidly invites disaster.

Further, fatigue and overexertion involve the likelihood of inspiration of the secretions of the nose and throat into the trachea and even into the bronchi, causing inspirational bronchitis or pneumonia. It is also assumed that the presence in the blood of katabolic products of muscular activity have an injurious action on the cells of the tissues in general and on the leukocytes and antibodies in particular. This diminution of immunity after muscular fatigue is manifested in animals as well as in man. White rats which have been made to work in a revolving cage are more susceptible to anthrax than normal white rats, the preëxisting immunity being broken down. There is experimental evidence suggesting that fatigue diminishes the amount or the activity of the antibodies in the blood; thus there seems to be reductions of lysins, antitoxins, agglutinins, and opsonins, with a weakening of the defensive powers of the body.

*Insufficient and unsuitable food* is a prime factor in undermining vitality and lowering resistance. The influence upon health of food poor in quality or lacking in quantity is a matter of common experience, but the scientific explanation of the way in which this result is brought about is not at all clear. First of all, it must be remembered that starvation or improper food does not depress immunity to all infections, but lowers resistance only to certain infections. It was for-

merly supposed that famine was the direct cause of pestilence. In fact, in India it has commonly been stated that "plague follows famine with some regularity," but we know now that plague in man is secondary to the disease in rats and is transmitted through the flea. Relapsing fever was formerly called famine fever, and outbreaks of typhus fever were frequently connected with famine, but we know now that the former is transmitted by the tick and the latter by the louse. It is evident that famine may be indirectly a cause of epidemic outbursts without necessarily depressing immunity, for it is accompanied by misery and squalor and an increase of vermin and other factors that favor the transmission of disease.

Tuberculosis, of all diseases, is favored by insufficient and unsuitable food. This is an infection in which poor nourishment lowers, and good nourishment raises, our resistance. Poor and insufficient food, however, is usually associated with poverty, insufficient clothing, uncleanly habits, vitiated atmosphere, overwork, insufficient rest, and other depressing influences, so that it is difficult to assign relative importance to any one of these factors. For this reason we may perhaps be led to exaggerate its importance; and, while it is, of course, true that semi-starvation, in common with other weakening influences, does pave the way for infective processes, we do not find that a supply of food restricted enough to cause a marked reduction of the bodily strength and some degree of anemia is necessarily associated with any infectious disease, though the patient may live under conditions in which infective material is present in abundance. This is well seen in fasting men, in hysterical anorexia, and in patients with impermeable esophageal strictures. The blood, it may be pointed out, is not one of the tissues that suffers first in starvation, and its importance to the body in many ways is so great that it is kept in good functional activity while other tissues waste quickly. Unbalanced diets lead directly to beriberi and pellagra, and are associated with scurvy, rickets, and other disorders of nutrition (pages 674-676). The importance of a well balanced and generous diet, especially for growing children, cannot be overestimated.

There is a general belief that exposure to infection is less dangerous after a meal than upon an empty stomach. There is little ground for this belief, unless we take into consideration the notable increase in the number of leukocytes in the peripheral blood during active digestion. It was recognized long ago that wounds inflicted during autopsies are much more dangerous when received while fasting than during the process of digestion, and it is possible that this may be due to some extent to the increased number of leukocytes which occur in the peripheral blood during digestion. Further, infection reaching an empty stomach has greater chances of passing into the small intestines than if it reaches the stomach after a full meal when acidity, time, and the

digestive enzymes have a chance to destroy the microörganisms. This may be of importance in cholera, typhoid, dysentery, and other intestinal infections.

*Exposure to a vitiated atmosphere*, if of long duration, is one of the potent causes of breaking down resistance. Here again, however, immunity is lowered in a special and not in a general sense. Thus, vitiated air renders the individual more susceptible to tuberculosis, pneumonia, common colds, and other acute respiratory affections. On the other hand, it has little influence in determining the infection of most of the communicable diseases, although the lowered tone of the body caused by vitiated air may influence the severity of the attack. The mechanism by which vitiated air increases susceptibility is not understood. The subject is discussed in Chapter IV upon Air.

*Excesses* of all kinds, symbolized by Bacchus, Venus, and Vulcan, are mighty factors in lowering vitality and in increasing susceptibility to certain diseases. In this category are also found worry, overwork, loss of sleep, and fatigue.

Certain *drugs*, of which the most important is alcohol, have an important action in lowering resistance. Emery states: "The liability of alcoholic subjects to pneumonia and some other infective diseases is well known, and in them the prognosis is more than usually unfavorable. We have but little knowledge of the action of alcohol in this respect. It may be that it acts as a direct inhibitant of the activity of the leukocytes, and it is known to destroy certain delicate defensive substances (alexins and opsonins) which play some part in the defense of the body against microbial invasion, but it is not known whether these effects are actually manifested in the circulating blood. It is also possible that alcohol tends to inhibit the formation of these defensive substances.

"Alcohol tends to lower the temperature of the body by increasing the amount of heat lost. It dilates the superficial vessels and accelerates the heart action in a way somewhat similar to muscular exercise, but does not, like it, raise the temperature of the interior of the body. Hence the effect of alcohol in conjunction with cold and wet is to increase their ill effects. More blood is forced through the chilled skin and more heat is lost. The injurious effect of alcohol during exposure to cold is well known."

**Relation between Host and Parasite.**—Infectious disease is not an entity, but a reaction resulting from the struggle between host and parasite. The story of the infectious diseases is that of a conflict between these two beings. In one sense this conflict, though less obvious, is not essentially different from the conflict between a rattlesnake and his prey. The battle between host and parasite results in a reaction in the host, and this reaction we call the disease. The various elements which make up

this conflict, such as the mode of attack of the parasite and the means of defense of the host, are being carefully studied. An active defense on the part of the host will sharpen the claws of the parasite in accordance with the laws of the survival of the fittest, and thus increase the reaction, i. e., the intensity, of the disease. If the parasite is unduly aggressive and virulent, and thus kills its host too quickly, it defeats its own object, for the parasite is in the position of the rats on a ship. It serves small purpose to scuttle the ship unless there is some means of passing to another ship. The mode of transference of the parasite is, therefore, of vital importance to the parasite, and of great practical concern to the host. The infectious diseases, then, represent only one phase in a complex series of events in which parasite and host are interrelated in ways often compared to seed and soil.

The invasion of the parasite and the reaction which occurs in the host may be understood by comparing an individual with a nation. A nation at peace with the world and in a state of healthy progress, corresponds to an individual in health. Suppose our nation is visited by an alien people, say the inhabitants of Mars, whom we will take to represent the parasite. They come few in numbers, are looked upon askance, but, being an unknown factor, no special measures are taken against them; meanwhile they grow and multiply. This is the period of incubation. In time they become numerous enough to threaten our homes and happiness. Then there is an uprising or warfare. The disease begins, it is a fight for who shall have possession of the land, that is, the host. If our enemies conquer, the disease has had a fatal termination, but if we conquer, and kill or drive off our enemies, complete recovery takes place. If a few of the enemy remain, we are in the condition of a bacillus carrier, subject not only to reinfecting ourselves, but endangering the peace and safety of the neighboring nations. After the battle has been fought and won it leaves us immune, in other terms, educated, for if this same strange race should again come to our shores they would at once be met with an immediate reaction and not allowed to enter our body politic.

**Ehrlich's Side-chain Theory of Immunity.**—Ehrlich's<sup>16</sup> side-chain theory is a chemical conception of some of the phenomena concerned in immunity. In one sense it has been likened to Weigert's teachings of inflammation and the process of repair in so far that cognizance is taken of nature's prodigality. For instance, a much larger amount of material is thrown out than necessary to repair a wound. So, too, in an-

<sup>16</sup> Ehrlich: "Die Wertbemessung des Diphtherieheilserums und deren theoretische Grundlagen." *Klin. Jahrb.*, Jena, VI (2), 1897, pp. 299-326.

titoxic immunity a much larger amount of antitoxin is produced than necessary to neutralize the toxin.

In Ehrlich's conception the fundamental processes of immunity reside in the cells of the body. These cells are attacked by the poison, and if not destroyed are stimulated to an overproduction of "antibodies" capable of combining with and neutralizing the poison.

Just what cells of the body play the most important rôle in the production of this form of immunity is not exactly clear. It may be, as Ehrlich supposes, that this power resides in any organ or tissue.

According to Ehrlich, the hungry protoplasm of any cell, with its complicated molecule, having side chains of various combining affinities ready to unite with suitable food molecules brought to it by the blood and body juices, lies at the foundation of his explanation of the chemical production of the antitoxin. It is strange that the same combining affinity should exist between the protoplasm of the cell and the proteid molecules that furnish it food, as between the cell protoplasm and the toxins of the bacterial poison.

In considering Ehrlich's<sup>17</sup> side-chain theory it is necessary to disregard the microscopic structure of the cell and to think of the protoplasm as consisting of living molecules of extraordinary chemical complexity. The molecule of protoplasm has a central "nucleus" with "side chains," "lateral chains," or "bonds" of varying combining capacities. These "side chains" serve to bind the molecule to other molecules having proper combining affinities.

This arrangement of molecules with side chains is a well-known occurrence in organic compounds. The benzol ring forms one of the best and simplest examples.

By replacing one of the H atoms in the benzol ring with the methyl radical ( $\text{CH}_3$ ) we have toluol; by replacing one of the H atoms with the hydroxyl group ( $\text{OH}$ ) we have phenol; by substituting two hydroxyl groups we have resorcin; three, pyrogallie acid, etc.; by substituting one hydrogen atom of the ring with the hydroxyl radical and another one with the methyl radical we have the cresols.

<sup>17</sup> Ehrlich: "Die Wertbemessung des Diphtherieheilserums und deren theoretische Grundlagen," *Klin. Jahrb.*, Jena, VI (2), 1897, pp. 299-326.

These simple illustrations from well-known organic compounds illustrate the central molecular mass with its side chains and combining affinities, to which the "molecule" of protoplasm is likened.

In applying this analogy to the molecule of protoplasm the name "receptor" is given these side chains, or secondary atomic complexes of the molecular group. Contrary to the simple analogies above given, each molecule of protoplasm has many different kinds of receptors, as shown by the schematic diagram in Fig. 52. These receptors have a specific affinity for the molecules of food, and also combine with the toxic molecules.

The *toxin* molecule, according to Ehrlich, consists of two important parts. One is known as the *toxophore* group, the other as the *haptophore* group. This conception is theoretical.

FIG. 53.—THE TOXIN MOLECULE; SHOWING THE HAPTOPHORE (COMBINING) GROUP, AND THE TOXOPHORE (POISON) GROUP.

The *toxophore* group of the *toxin* is that portion of the molecule which exerts a poisonous effect upon the protoplasm of the cell. This group is less stable than the *haptophore* group.

The *haptophore* group is the seizing or combining portion of the *toxin* molecule (*ἄπτείν*, to seize or attack). The *haptophore* group of the *toxins* have specific combining affinities for the receptors of certain cells, which in part explains the selective action of these

poisons.

Toxines such as diphtheria toxine gradually diminish in toxicity, but retain the same power of chemical combination with the antitoxin. This phenomenon explains the formation of *toxoids*.

Ehrlich inferred the presence of the *toxoid* from the following simple experiment: He had a toxine which required 0.003 c. c. to kill a guinea-pig. After nine months this poison weakened, so that it required three times as much, that is, 0.009 c. c., to kill a guinea-pig. Nevertheless, the combining power of the toxine for antitoxin remained the same.

*Toxoids* are altered *toxins*. They consist of the toxic molecule in

FIG. 52.—THE CELL WITH ITS VARIOUS COMBINING GROUPS OR SIDE CHAINS, KNOWN AS RECEPTORS. Various toxins are shown having specific affinity for the proper shaped receptors.

FIG. 54.—THE FIRST STAGE OF ANTITOXIN FORMATION: A TOXIN MOLECULE ANCHORED TO A RECEPTOR.

which the toxophore group has been weakened, leaving intact the haptophore or combining group, which, while able to satisfy the combining affinities of the antitoxin, is no longer as poisonous to the protoplasm of the cell.

The diphtheria bacillus, during the process of its growth and multiplication in the body or in an artificial culture medium, produces several poisons, one of which is known as diphtheria *toxin*. As above stated, the diphtheria *toxin* consists of a toxophore and haptophore group. In the body the latter unites chemically with the receptors of the cells. When this takes place one or two consequences may result: either (1) the cell is so severely poisoned that it dies, or (2) the living molecule of protoplasm is stimulated so as to excite a defensive action by the reproduction of its receptors. Continued stimulation produced by the periodical injection of toxine results in an overproduction of receptors, which finally loosen and float free in the blood serum and body juices. Receptors fixed upon the cells are called *sessile*, and those that leave the cell are spoken of as *free* receptors.

Antitoxin consists of these free receptors floating in the blood serum. If we now introduce *toxin* into the blood, it is immediately neutralized by combining with the free receptors through its haptophore group. All the combining affinities of the *toxin* are thus satisfied or saturated, so that the *toxin* is no longer able to unite with the receptors still attached to the cell, and the poison is thus rendered harmless.

It is by no means a necessary corollary of the side-chain theory, as is often supposed, that the receptors are found only in those organs upon which the poisonous effects of a toxin are particularly manifested. On the contrary, Ehrlich and Morgenroth<sup>18</sup> believe that receptors capable of combining with the *toxin* are produced in many different parts of the body, especially in tissues and organs having the power of anchoring the *toxin* without producing serious poisonous effects.

The connective tissue is believed to be specially rich in receptors, evi-

FIG. 55.—THE SECOND STAGE: CONTINUED STIMULATION CAUSES A REPRODUCTION OF RECEPTORS.

FIG. 56.—THIRD STAGE: THE RECEPTORS BEGINNING TO LEAVE THE CELL.

<sup>18</sup> Ehrlich, P., and Morgenroth, J.: *Wirkung und Entstehung der aktiven Stoffe im Serum nach der Seitenkettentheorie*. Handbuch der pathogenen Mikroorganismen, W. Kolle, and A. Wassermann, Jena, 1904.

denced by the local reaction caused by the subcutaneous inoculation of diphtheria toxine, ricin, abrin, and similar poisons. In fact, one would not be far wrong in assigning a particular significance, in the production of receptors, to just those organs which show unimportant vital response, because in such tissues the injurious effects of the toxophore group are absent or of such diminished importance that the regenerative powers of such tissues are not retarded.

The presence or absence of receptors capable of binding the toxine, as well as their number and distribution, are factors which

FIG. 58.—THE NEUTRALIZATION OF A TOXIN BY ANTITOXIN; THE FREE RECEPTORS IN THE BLOOD HAVE UNITED WITH THE TOXIN—ANTITOXIC IMMUNITY.

determine the susceptibility of different species of animals to the various toxins. These factors also determine the individual variations in the susceptibility to poisons and further explain some instances of natural immunity to toxins.

An example is given by Sachs,<sup>19</sup> who studied the reaction of guinea-pig blood against arachnolysin, a toxin found in spiders. In this case the complete immunity of the red blood cells of the guinea-pig against arachnolysin is accounted for by the entire absence of the proper receptors, while the susceptibility of the red blood cells of the rabbit to very small quantities of this poison is accounted for

by the strong combining affinity which exists between these cells of the rabbit and the arachnolysin.

The union between the receptor of the cell and its poison is not always a direct one, as described above, but sometimes takes place through the intervention of an intermediary body, known variously as the amboceptor, *Zwischenkörper*, immune body, sensitizer, fixative, preparative, desmon, etc.

This second order of immunity is particularly evident in the poisons that have a lytic or dissolving action upon bacteria or the cells of the body, such as the bacteriolysins, hemolysins, and other cytolsins. The poisonous bodies in this order of immunity are usually spoken of as "complement," but also as the "alexin" (Buchner) or "cytase" (Metchnikoff).

<sup>19</sup> Sachs, Hans: "Hofmeister's Beitr.," Bd. 2, H. 1-3.

FIG. 57.—FOURTH STAGE: THE RECEPTORS HAVE LEFT THE CELL AND FLOAT FREE IN THE BLOOD—ANTITOXIN.

FIG. 59.—SHOWING COMPLEMENT AND IMMUNE BODY.

It became necessary for Ehrlich to modify and extend his theory in order to explain phases of antibody-antigen reactions other than the simple toxin-antitoxin combination.<sup>20</sup> For this purpose, Ehrlich conceived three main varieties or "orders" of receptors. Of these the simplest are those of the *first order*, which attach to the toxins and by over-regeneration appear in the blood stream as antitoxins. Those of the *second order*, adapted to the assimilation of more formidable protein molecules, are of necessity of greater structural complexity and appear in immunized animals as the agglutinins and precipitins. Those of the *third order* are dependent upon the coöperation of complement for proper functioning and appear as the cytotoxins or lysins.

One of the remarkable facts connected with the phenomena of the lytic poisons is that the poison itself (the complement) is normally present in the blood. Complement is thermolabile, that is, it has less resistance to heat than the intermediary body, which is thermostabile. According to Ehrlich's theory, immunity can only be obtained by means of the intermediary body, which is believed to be specific.

FIG. 60. — SHOWING AN IMMUNE BODY HAVING TWO AFFINITIES.

Ehrlich compares the intermediary body with diazobenzaldehyd, which by means of its diazo group is capable of combining with a series of bodies, such as aromatic amins, phenols, ketomethyl bodies, etc., while by means of its aldehyd group it may combine with a different series, such as the hydrazins, ammonia radicals, and hydrocyanic acid. Phenol and hydrocyanic acid will not directly combine, but, with diazobenzaldehyd acting as an intermediary body, these two substances can be brought into combination.

Pushing this comparison further, we may say that the aromatic body, or the phenol, represents a constituent of the blood corpuscle. The diazobenzaldehyd is the intermediary body, while the poisonous hydrocyanic acid constitutes the complement.<sup>21</sup>

Welch<sup>22</sup> very ingeniously extended Ehrlich's conception of immunity to the bacterial cell. According to Welch's views, the bacterial cell has the same power of defensive action against the poisons produced by the cells of higher animals that they have against the toxic products of the bacteria. This chemical conception of immunity has been helpful, but doubtless it is not the final explanation, for we now think of the mechanism of immunity more in terms of physical states of a colloidal nature.

<sup>20</sup> For every phenomenon it has been necessary for Ehrlich to invent a phenomenon.

<sup>21</sup> Vaughan and Novy: "Cellular Toxins," 1902, p. 131.

<sup>22</sup> Welch, William H.: "Huxley lecture on recent studies of immunity with special reference for their bearing on pathology." *Bull. Johns Hopkins Hosp.*, Baltimore, XIII (141), Dec., 1902, pp. 285-299.

In other words, there is a chemical battle. Both the bacterial cell and the body cell excrete poisonous substances against each other, and both in turn are building up a chemical defense against the action of these respective poisons.

**Antitoxic Immunity.**—In order to understand antitoxic immunity it is necessary to consider the nature and action of toxins, the formation and production of antitoxins, and the reaction between toxins and antitoxins.

## TOXINS

Bacteria produce many different kinds of poisonous substances, but not all of these are toxins in the specific sense in which that term is now used. A *toxin* may be defined as a specific poison elaborated by bacterial metabolism; it is soluble in water; poisonous in minute amounts; reproduces the essential symptoms and lesions of the disease; acts only after a period of incubation; and produces antibodies, namely, antitoxin. The toxins are thermolabile, unstable, and have a complex chemical structure.

Toxins are known only by their effects upon animals; they cannot be recognized in any other way. Presumably they belong to the higher proteins, but nothing definite can be stated concerning their chemical structure. They have never been isolated in pure form; they are not toxalbumins, as was once believed, and they only have a remote analogy to the enzymes. Toxins may be globulins, at least they come down in the globulin fraction. They may readily be precipitated with ammonium sulphate, for example, but whether they are mechanically carried down in the precipitate is not known. The toxin molecule is at least small enough to pass readily through the pores of the finest porcelain filter, and large enough not to dialyze through a membrane.

There are three well-known toxins: diphtheria, tetanus, and botulinus. Toxins are also produced by *B. perfringens* (Welch) and other anaërobes. A number of bacteria, such as cholera, dysentery, pyocyanus, and others, produce a certain amount of toxic substances soluble in water, but it is very doubtful whether they are true toxins in accordance with the above definition. Bacteria produce many poisonous substances other than the true toxins, such as acids, alkalies, nitrites, ferments, alcohol, hydrogen sulphid, etc. Some of these substances may play a part in the pathogenesis of disease.

Some organisms produce both endo- and exo-toxins; thus, two toxic substances have been demonstrated by Oltitzky and Kligler<sup>23</sup> in filtrates of the dysentery bacillus; (1) an exotoxin, which acts especially upon the nerves and is therefore called a neurotoxin; (2) another, which is probably an endotoxin, acts upon the intestinal tract and is therefore an

<sup>23</sup> *Journ. Exp. Med.*, Jan. 1, 1920, XXXI, 1, pp. 19-33.

enterotoxin. Toxins are sometimes divided into *exotoxins* and *endotoxins*. The former are the true or soluble toxins; the latter are insoluble under ordinary circumstances, and differ markedly from the true exotoxins. The endotoxins will be considered separately.

The tubercle bacillus, the bacillus of glanders, and other microorganisms produce soluble toxic substances specific in nature but quite different from the true toxins, in that they are harmless to a normal animal, but poisonous to one suffering with the specific disease. Tuberculin, mallein, and similar so-called "toxins" are very stable, resist heat and other influences, do not produce the specific lesions and symptoms of the disease, and do not stimulate antitoxin formation. They are not toxins.

A toxin is produced as a result of bacterial metabolism, but whether it is a secretion, an excretion, or a product of the action of the bacteria upon the medium (as alcohol and carbon dioxide are produced by yeasts) is not known. It is known, however, that toxins do not result simply from the breaking down of the dead bacterial cells, as was once stated.

It is now evident that different groups of bacteria produce poisons that differ essentially in chemical structure as well as in physiological action, just as different species of higher plants produce various poisons that differ markedly in composition and physiologic action. Some bacteria produce more than one toxin; thus, diphtheria bacilli produce toxin and toxogen; tetanus produces tetanospasmin and tetanolysin; dysentery produces an enterotoxin and a neurotoxin, etc.

Very few of the bacterial poisons are injurious when taken by the mouth. Diphtheria and tetanus toxins are practically inert, being destroyed largely by the digestive juices and not being absorbed in any harmful amount. Enormous doses of these toxins may be administered by the mouth to susceptible animals without appreciable harm. There is one notable exception in the case of the toxin of the *Bacillus botulinus*, for this poison is absorbed by the digestive mucosa, and it is in this way that it produces its harmful effects in man.

There are several poisons produced by higher plants that resemble the true bacterial toxins in all important respects. Among them are: *ricin* from the castor bean, and *abrin* from the jequirity bean. These toxins of vegetable origin are known as phytotoxins. They are soluble, act only after a period of incubation, are exceedingly poisonous in small amounts, are destroyed by heating, and produce specific antibodies. They are probably of protein nature, according to Osborne, Mendel, and Harris, who obtained ricin in very pure form. These poisonous substances of vegetable origin have more than theoretical interest, for it was through a study of their action that Ehrlich first obtained a deeper insight into the nature of toxins and antitoxic immunity.

There are poisons in the animal kingdom which closely resemble the toxins, such as the venom of snakes, scorpions, spiders, wasps, etc.

True toxins are unstable and are readily affected by heat, sunlight, acids, and various chemicals. They are much more unstable in solution than in dry powdered form. Tetanus toxin is more labile than diphtheria toxin, but when precipitated with ammonium sulphate and preserved as a dry powder in a vacuum tube, and in a cool, dark place it may be kept without deterioration for several years. Diphtheria toxin, in solution, weakens rapidly at first, and then comes to a stage of equilibrium which it maintains indefinitely if preserved in a cold, dark place and protected from the oxygen of the air.

The poisonous properties of toxins of diphtheria, tetanus, and botulinus are destroyed at once by boiling, and at 75° C. in a short time. At 60° C. for one hour they lose most or all toxic power.

It has been stated that one of the characteristics of the toxins is that they are poisonous in exceedingly small amounts. Thus, .000,000,05 gram of a partially purified tetanus toxin will kill a mouse. Diphtheria toxins have been obtained so that .0008 c. c. of the unconcentrated fluid (crude filtrate) will kill a guinea-pig.

A true toxin reproduces the true symptoms and essential lesions of the disease. In this sense they have a specific action. The symptoms produced in a susceptible animal by the inoculation of tetanus toxin cannot be distinguished from the disease naturally contracted. The symptoms produced by the injection of diphtheria toxin closely resemble diphtheria, including coagulation necrosis at the site of the injection, fever, depression, postdiphtheritic paralysis, etc. The symptoms following the ingestion of the toxin of the *Bacillus botulinus* are an exact counterpart of the disease. This specific action is very important, and, if it were more generally known, would save many mistakes in experimental biology and its application to serum therapy. It is comparatively easy to obtain useful antitoxins from true toxins. On the other hand, it seems to be impossible to obtain antitoxins of any therapeutic potency from other bacterial poisons. Thus, tuberculin and mallein and other so-called "toxins" do not stimulate production of antitoxin and the sera thus produced have no protective or curative value. Certain antigens, as the pneumococcus and meningococcus, produce antibodies with protective properties—but these antibodies are not antitoxins. It must not be forgotten that the lesions and symptoms of but a few infections depend upon true toxins and may be prevented or cured by corresponding antitoxins.

One of the characteristics of the true toxins is that they act only after a period of incubation. In this respect they resemble the natural disease. Simple chemical poisons may act at once, but the toxins produce no apparent effect until a definite time elapses after they have been intro-

duced into the system—even when overpowering doses are administered. Thus, the ordinary period of incubation when tetanus or diphtheria toxin is injected into a susceptible animal is several days. When enormous amounts are injected this may be reduced to about 8 or 12 hours, but never less. In botulism the symptoms may appear in a few hours. The period of incubation is inversely proportional to the amount of poison injected. The longer the period of incubation the milder the symptoms; when the period of incubation is short the result is almost invariably fatal. The cause of the period of incubation is not well understood. A certain length of time is required for the toxin to reach the susceptible cells. This varies especially in the case of tetanus, which travels up the nerves. After the poison reaches the cells further time is required to combine chemically, and then more time to produce the injury. On account of the period of incubation large amounts of toxin may be present in the circulating blood before the appearance of the symptoms. Thus, in horses enough tetanus toxin has been found in the blood two days before the onset of symptoms to kill a guinea-pig, when only 0.1 c. c. of the blood serum of the horse was injected into the guinea-pig.

The distribution of the toxins in the body is unequal. Most of the poison unites with the cells; some is destroyed and some neutralized if antitoxin is present. Most of it probably unites with the cells, as it soon disappears from the blood. Tetanus toxin may remain a long time in the blood of an insusceptible animal. Thus, Metchnikoff could demonstrate the presence of tetanus toxin in the tortoise four months after the injection. After tetanus toxin is injected it soon disappears from the blood, but if the tissues are injected into a susceptible animal tetanus is produced, for it is now known that this poison has a specific affinity for the motor nerve endings. In the case of fowls it seems that this power of combining with the tetanus toxin is most marked in the leukocytes. Toxins will not combine with all cells indifferently. They have a specific combining affinity for certain cells. Tetanus toxin has a special affinity for the cells of the central nervous system. Diphtheria toxin also acts specifically upon nervous structures; it is also a general protoplasmic poison. These facts are of immense importance in the prevention and cure of certain infections, for a correct understanding of the chemical relation between the poison and the particular cell is of the greatest fundamental and practical value. A realization of this fact has stimulated studies which are now in progress upon the relation between the chemical constitution and the physiological action of various substances—studies which have already borne fruitful and useful results.

Tetanus toxin may combine with certain cells without apparently injuring them. Diphtheria toxin also combines with indifferent structures, such as the connective tissue. There is evidently a wide difference between the power to combine and the power to injure. The power to

injure, however, is not always evident, as it depends upon the importance and extent of the cells affected. Thus, tetanus toxin may combine with the leukocytes in such a way as to prevent phagocytosis. This may be demonstrated by injecting tetanus spores washed free of toxin, in which case the spores are taken up by the leukocytes and their development is prevented. If, however, a slight amount of toxin is injected with the spores, the poison inhibits phagocytosis and permits the growth and multiplication of the tetanus microorganisms and the further production of toxin.

From one standpoint the most important property of a true toxin is its power to produce specific antitoxins. This will be given separate consideration.

Ehrlich conceives the toxin to be a complex molecule containing both a haptophore and a toxophore group. The haptophore, or seizing, group is that part of the molecular structure which combines in a chemical sense with the antitoxin or with the receptors of the cell. The toxophore group is the poisonous part of the toxin molecule. This is usually represented diagrammatically. See Fig. 53, page 549.

It may readily be demonstrated by simple experiments that the toxophore group is much more unstable than the haptophore group. The toxin may degenerate so that it has little or no poisonous properties left; however, its combining properties remain unaltered. Such a degenerated toxin is known as a *toxoid*. A toxoid, then, is an altered toxin which possesses the combining property of the original toxin, but has lost its poisonous power. Some years ago I proposed to draw a distinction between the terms "toxine" and "toxin." The *toxine* is the crude filtered culture and contains several poisonous substances as well as other bodies. The *toxin* is the specific poison in the *toxine*. Thus, a filtered broth culture of diphtheria is known as diphtheria *toxine*. This filtrate contains at least two primary metabolic poisons: *toxin* and *toxon*. The *toxin* produces the acute symptoms and death; the *toxon* produces the late paralysis. A filtered broth culture of tetanus is called the tetanus *toxine*. The filtrate contains at least two primary metabolic poisons: tetanoplasmin and tetanolysin.

## ANTITOXINS

An antitoxin is an antibody formed in an animal through the stimulation of a specific toxin. The usual method of producing an antitoxin is by the repeated injections of increasing amounts of *toxine* into a susceptible animal. The strongest antitoxins are obtained from animals that are very susceptible to the *toxine*, but all susceptible animals by no means produce antitoxins, although repeatedly injected with the

appropriate poison. Thus, a guinea-pig which is very susceptible to diphtheria will not form diphtheria antitoxin, even after the repeated administration of diphtheria toxine. Guinea-pigs are also exceedingly susceptible to tetanus and react characteristically and violently to tetanus toxine, but the repeated injections of subminimal lethal doses of tetanus toxine into a guinea-pig do not immunize that animal, nor do they induce the formation of antitoxin. In fact, Knorr and also Behring and Kitashima have shown that guinea-pigs develop an increasing sensitiveness to repeated injections of tetanus toxine instead of an increasing resistance. In other words, the guinea-pig, a susceptible animal, lacks the mechanism of antitoxin formation which is possessed in such a high degree by horses and other animals. Antitoxin produced by the horse or other animal when injected into the guinea-pig will protect it.

On the other hand, insusceptible animals, as a rule, do not produce antitoxin, but there are notable exceptions to this rule. Metchnikoff has shown that the cayman, an animal insusceptible to tetanus, will, however, produce tetanus antitoxin if the animal is kept at an elevated temperature ( $32^{\circ}$  to  $37^{\circ}$  C.), but not if kept cold ( $20^{\circ}$  C.). The mechanism of antitoxin formation is not understood, and the only way of determining whether a certain species of animal is suitable or not is by experimental trial. There is a very great difference in the ability to produce antitoxin even among different individuals of a suitable species. Thus, some horses have this power developed to such an exquisite degree that they produce a high grade of antitoxin for prolonged periods—years. Other horses make comparatively weak antitoxin. This difference among horses is well known to manufacturers, who have no means of knowing beforehand which horses will be profitable.

There are several reasons for selecting the horse for the production of immune sera for human use. On account of its size it furnishes large quantities of blood; the serum of the horse is the blandest blood serum of any known species; finally, the horse furnishes antitoxin in higher potency than any other known animal.

Just how and by what cells antitoxins are formed in the body is not known. They are not formed directly from the toxins. In some way the toxine excites the cell to the formation of the antibody. The antibody leaves the cell and becomes "dissolved" in the blood and tissue juices. Perhaps the white blood cells (Metchnikoff), perhaps the connective tissue cells (Ehrlich), are chiefly concerned. Within the body most of the antitoxin is found in the blood, but it also exists in greater or less concentration in practically all the fluids of the body and may also appear in the excretions, as the urine, saliva, milk, and bile.

Nothing definite can be stated concerning the chemical nature of antitoxins. Evidence strongly points to the fact that they belong to the higher proteins. In all probability antitoxins are globulins, at least

they come down with the pseudo-globulin fraction from which they have not been separated.

Antitoxins are somewhat more stable than the toxins. Further, the toxins have a more complex constitution than the antitoxins. When the toxins deteriorate they change qualitatively as well as quantitatively. The antitoxins have a simpler constitution and deteriorate simply by a loss of power.

Antitoxins are destroyed by heat, acids, and many chemicals. They gradually deteriorate spontaneously when in solution. Thus, Anderson has found that the average yearly loss of the potency of diphtheria antitoxin at room temperature is about 20 per cent.; at 15° C. it loses about 10 per cent.; and at 5° C. about 6 per cent. There is little difference between the keeping qualities of untreated sera and concentrated sera. Dried diphtheria antitoxin kept in the dark at 5° C. retains its potency practically unimpaired for at least 5½ years. Antitoxic sera should always be kept in a cool, dark place. While antitoxin loses some of its potency with time, and while recently tested sera of known unit value are always desirable, there is absolutely no reason why a serum, however old, should not be employed provided a fresh supply is not at hand. It should be remembered that antitoxins deteriorate quantitatively only; in other words, an old antitoxin is quite as useful in proportion to its unit strength as a fresh serum; in fact, antitoxic sera are frequently two years old when placed upon the market by manufacturers.

Antitoxins are strictly specific; that is, they neutralize the corresponding toxine and have no other apparent action within the body. The occasional ill effects, such as the serum sickness, following the injection of antitoxic sera, are due to other substances (the proteins in the serum) and not to the antitoxins themselves. Tulloch<sup>24</sup> on the basis of agglutination tests has separated tetanus cultures into four types. Fortunately, any one of the four antitoxins will neutralize any or all of the four toxins. It is, however, advisable to prepare the antitoxin with the four different types.

Antitoxins may be injected subcutaneously, intravenously, into the subarachnoid space, into muscle, into the brain substance, or into any of the body cavities. Antitoxins are practically useless when given by the mouth, as very little is absorbed. Antitoxins when injected into an organism disappear rather quickly. Some of the antitoxin is bound to the corresponding toxine, if any is present, some combines with the cells, but the greater part is eliminated as antitoxin in the urine, bile, saliva, etc. The antitoxin produced actively by the body as a result of an attack of disease, or stimulated by the injection of toxine, is formed continuously and confers an immunity for an indefinite period. Passive

<sup>24</sup>Proc. Royal Soc., Series B, April, 1918.

or antitoxic immunity is, on the other hand, transient; it cannot be depended upon for more than ten days or two weeks.

Some persons have sufficient native antitoxin in their blood to protect them against diphtheria. This has been demonstrated through the Schick reaction (see page 201). In such cases the antitoxin is produced naturally for long periods, often during the life-time of the individual.

When antitoxic serum is injected subcutaneously the antitoxin is absorbed slowly. It requires about 48 hours under these circumstances for the antitoxin to appear in the blood in maximum amount. Therefore, when very prompt action is desired, the antitoxic serum may be introduced directly into the circulation by intravenous injection.

There are a number of antibodies that are either true antitoxins or closely resemble these antibodies. Some of these antibodies neutralize the true bacterial toxins, others the poisons of animal origin, others the poisons of plant origin, and others neutralize the activity of ferments. The principal antitoxins, according to this classification, are brought together as follows:

(1) *Bacterial Antitoxins*.—The three principal and most potent bacterial antitoxins are those of diphtheria, tetanus, and botulinus. The following are also considered to have antitoxic properties: pyocyaneus, symptomatic anthrax, antileukocidin and antilysin against bacterial hemolysins.

(2) *Animal Antitoxins*.—These antitoxins are produced by animal poisons belonging to the venoms. True antibodies are obtained against snake venom and similar poisons in spiders, eels, wasps, scorpions, fish, salamanders, and toads.

(3) *Plant Antitoxins*.—These are antiricin, antiabrin, antirobin, and anticroton.

(4) *Ferment Antitoxins*.—Antibodies may be obtained against ferments, such as pepsin, urease, rosinase, steapsin, trypsin, fibrin ferment, lactase, cyranase; and antibodies may also be obtained against the enzymes found in bacterial cultures.

There are comparatively few antitoxic sera of practical use in human therapy, just as there are relatively few true bacterial toxins. The best known antitoxins are those of diphtheria, tetanus, and botulinus. Numerous other antitoxic sera are found upon the market or have been described, but they are of doubtful value.

Antitoxins are valuable both as curative and immunizing agents. Their preventive action depends upon the fact that they meet the toxin, unite with and neutralize it, thus rendering it harmless. As already stated, the antitoxins remain in the body a brief time and their immunizing power, while of a high grade, is transitory. They disappear in about ten days or two weeks; the immunity must, therefore, be renewed

in special cases by repeated injections of the antitoxin until the danger is passed. This phase of the subject is considered in more detail under the prevention of diphtheria and tetanus. The usual immunizing dose for diphtheria is 1,000 units, for tetanus 1,500 units.

As a curative agent antitoxin must be administered early and in sufficient amount to insure success. It is most important to give the antitoxin early—before the damage is done. Too great emphasis cannot be laid upon this point. After the toxin has united with the cells it cannot be dislodged by the antitoxin. The importance of giving antitoxin early is well illustrated in the case of diphtheria. When moderate amounts (3,000 to 10,000 units) are injected on the first day of the disease the mortality is practically nil. The mortality increases with each hour's delay.

The importance of giving this sovereign remedy early is also illustrated in the experiments of Rosenau and Anderson<sup>25</sup> upon the influence of antitoxin upon postdiphtheritic paralysis. It was found that one unit of antitoxin, given not less than 24 hours after a fatal dose of diphtheria toxine in a guinea-pig, greatly modified the postdiphtheritic paralysis and saved the life of the animal, whereas 4,000 units given 48 hours after the infection did not modify the paralysis or save the life of the animal. Four thousand units of antitoxin is an enormous amount for a guinea-pig weighing about one-half pound. Weight for weight, it corresponds to 400,000 units for a 50-pound child. The fact that one unit of antitoxin saves life when administered timely, whereas enormous doses fail totally when delayed, should be sufficient to place physicians on their guard; increased dosage cannot atone for delay. When cases are seen late in the progress of the disease it is good practice to give the serum intravenously, so as to neutralize the toxin at once and prevent further damage. If given subcutaneously, further delay results on account of the time necessary for absorption. Tetanus antitoxin is a very valuable immunizing agent, but is of less value after symptoms have appeared, for then most of the damage has been done.

**Preparation of Antitoxin.**—The antitoxin used in human therapy is practically always contained in the blood serum or blood plasma of the horse. The blood is drawn from the jugular vein into sterile bottles. The bleeding should never be done until a week or more has elapsed after the last injection of toxine, so as to allow time for the disappearance of the poison from the circulation. The horses are given no food for about 24 hours preceding the bleeding, so that the blood may not contain the fresh products of digestion and metabolism. After the blood is drawn it may be allowed to clot spontaneously. In the case of horse blood this takes place more quickly at room temperature than in the ice chest.

<sup>25</sup> *Hyg. Lab. Bull.*, No. 38, 1907.

The clot is allowed to contract for a few days and the serum containing the antitoxin is then drawn off with a pipet or simply decanted. In this way a clear transparent serum is obtained which, if protected against contamination by the usual bacteriological precautions, is sterile and may be preserved indefinitely. It is almost a universal practice, however, to add a preservative; either chloroform (0.3 per cent.), phenol (0.5 per cent.), or cresol (0.4 per cent.). These preservatives in the amounts named are harmless when injected and have practically no effect upon the antitoxin itself. They gradually precipitate the albuminous matter from the serum, which settles as a white amorphous deposit and which may be disregarded, as it is harmless. Chloroform produces a better-looking serum, but the less volatile preservatives are usually preferred on account of their stability and, hence, greater reliability.

By the method of allowing the blood to coagulate, as above described, only about one-third of its volume is recovered as antitoxic serum. A much greater yield may be obtained by citrating the blood: sodium citrate prevents the clotting of blood. A solution of this salt is placed in the bottle which is to receive the blood directly from the horse, in sufficient amount to be present in 1 per cent. of the whole blood. The corpuscles soon settle to the bottom, leaving the clear supernatant plasma, which is then decanted or drawn off with a pipet. In this way the yield of antitoxic fluid is about 90 per cent. of the volume of the blood, and is, therefore, preferred to the less economical method of allowing the blood to clot.

The citrated plasma may further be "purified" or concentrated by various methods, that generally used being a modification of Gibson's<sup>28</sup> method, based upon the earlier experiments of Atchinson.

Ordinary antitoxic serum contains serum globulins (antitoxic), serum globulins (non-antitoxic), serum albumins (non-antitoxic), serum nucleoproteids (non-antitoxic), cholesterin, lecithin, traces of bile coloring matter, traces of bile salts and acids, traces of inorganic blood salts, and other non-proteid compounds. Refined serum contains serum globulins (antitoxic), traces of serum globulins (non-antitoxic) dissolved in dilute saline solution.

**Method of Concentrating Diphtheria Antitoxin.**—The Banzhaf modification of the original Gibson method for concentrating antitoxic serums is based on the fact that the antitoxin is contained in the pseudoglobulin fraction of the serum, and has as its purpose the isolation of the antitoxic pseudoglobulin from the non-antitoxic euglobulin, albumin and other serum constituents. Plasma, instead of serum, is used for reasons of convenience and economy. By adding ammonium sulphate to the diluted plasma up to about 30 per cent. saturation and heating the mixture to 60° C., the euglobulin and converted non-antitoxic pseudo-

<sup>28</sup> *Jour. of Biolog. Chem.*, Vol. I, 1906.

globulin are precipitated, and removed by filtration. By raising the saturation of the filtrate to about 50 per cent. with ammonium sulphate, the antitoxin is precipitated. This is collected on filters, pressed, and dialyzed in parchment bags until all the antitoxin is in solution and free from ammonium sulphate. It is then neutralized and brought to isotonicity with the blood by sodium chlorid, and a preservative added. It is filtered first through pulp and finally through a Berkefeld filter.

This method entails a loss of about 25 per cent. of the antitoxic units, but results in a five- or six-fold concentration of the antitoxin. The process of concentration makes it possible to utilize serum of low potency; it enables one to give large doses of antitoxin in small volume; and eliminates the bulk of serum proteins responsible for reactions and for serum sickness.

**Mode of Action.**—The mode of action of antitoxins is now fairly well understood. One thing is certain, and that is that the antitoxin unites directly with the toxin. This may be readily demonstrated by adding a little antitoxin to some toxin in a test tube and then injecting the mixture into a susceptible animal; no symptoms result. Diphtheria antitoxin combines with diphtheria toxin more quickly than tetanus antitoxin combines with its toxin. Thus, in the case of diphtheria the union between the toxin and its antibody is complete in less than twenty minutes at room temperature, while in the case of tetanus it requires one hour. These facts are of practical importance in the work of standardization, in which case the toxines and antitoxins are mixed in the test tube and the combining action must be complete before the mixtures are injected into the test animals in order to insure accurate results.

Ehrlich believes and strongly defends his assumption that an antitoxin unites with a toxin just as an acid unites with an alkali, that is, the one has a strong chemical affinity for the other, and the union is simple and direct. The reaction is complicated only on account of the complex nature of toxine. According to Ehrlich, there are two primary metabolic poisons in a filtrate of a culture of *B. diphtheriae*: (1) *toxin*, a poison which produces a local destruction of tissue and acute death; and (2) *toxon*, a nerve poison that produces late paralysis. There is also a modified toxin, known as *toxoid*. Toxin is more actively poisonous and also has a greater affinity for antitoxin than toxon, which it is able to displace from its combination with antitoxin. This explains in part the discrepancy between the  $L_0$  and the  $L_+$  doses. Ehrlich believed that the union of filtrate with antitoxin seems to occur in multiple proportions resembling valencies.

On the other hand, Arrhenius and Madsen insist that, instead of considering the toxine as a complex mixture of various substances, such as a toxin, toxon, etc., it would be simpler to consider it as a single (at

least homogeneous) substance which has a very weak affinity for the antitoxin and that in mixtures containing toxin and antitoxin there are always both free toxin and free antitoxin. Arrhenius draws his analogy from known facts in physical chemistry, particularly from studies upon the relation between solutions of boracic acid and ammonia. These two substances have a comparatively weak affinity for each other, and in mixtures all the boracic acid does not combine with all the ammonia, but there are always present both free ammonia and free boracic acid.

When ammonia and boracic acid are brought together in watery solution some of the ammonia at once unites with some of the boracic acid to form ammonium borate. This reaction starts with a certain velocity, but as the mass of ammonium borate increases the velocity of the reaction gradually diminishes. After a time a condition is reached when the ammonium borate has a maximum value and does not further increase, no matter how long the reaction is allowed to proceed under the given conditions.

When this condition of equilibrium is reached the mass contains a certain quantity of water, ammonia, boracic acid, and ammonium borate; but these substances are not at rest. The ammonia and boracic acid will always react when in the presence of each other, whether or not ammonium borate is present. But, as the appropriate amount of ammonium borate remains constant, it is understood while this continuous association between the ammonia and the boracic acid is going on there is at the same time a reversible action—that is, a dissociation of the ammonium borate to re-form ammonia and boracic acid. These two reactions take place simultaneously.

Arrhenius believes that the diphtheria poison changes slowly according to the laws of monomolecular reactions, that the toxin combines feebly with the antitoxin, the equilibrium constant being equal for both. The claim, however, that the toxin is a simple substance having a weak affinity for the antitoxin and that the combination of toxin and antitoxin follows the Guldberg-Waage law, and that the reaction is, therefore, reversible, seems untenable in the light of the evidence brought forward by Ehrlich, Nernst, Michaelis, and others.

Another view which seems to be gaining ground, as the analogy between reactions of immunity and those of colloids in general is being established more definitely, is that of Bordet.<sup>27</sup> According to this author, the toxin does not combine with antitoxin according to the laws of proportions as typical for chemical reactions, but the antitoxin distributes itself equally upon all the molecules of toxin present. Thus, if the amount of antitoxin present is not sufficient to neutralize all of the toxin, all of the molecules of toxin become partially saturated with the

<sup>27</sup> Ann. Inst. Pasteur, 1903, Vol. 17.

antitoxin. Accordingly, there can be any number of degrees of saturation before a complete neutralization of toxin by antitoxin is reached. This process can be likened, according to Bordet, to the saturation of starch with iodine. The starch particles can absorb variable amounts of iodine and accordingly will present different intensities of color. Bordet speaks of this process as being based on "adsorption" and not on chemical combination between toxin and antitoxin.

## ENDOTOXINS

In contradistinction to the soluble or exotoxins, there is a group of poisons known as endotoxins. The existence of endotoxins was taken for granted before they were actually demonstrated. As soon as it was found that only some bacteria produce soluble specific toxins it was at once assumed that the other bacteria must contain similar poisons, but closely bound within the cell and insoluble in ordinary culture fluids. It was further assumed that these endotoxins were in some way set loose in the body and thereby produced the lesions and symptoms of the disease. The endotoxins are conceived to be poisons very closely bound up with the protein contents of the bacterial cell, and are liberated in the body when the bacterial cell dies and disintegrates. However, it by no means follows that these endotoxins are poisons similar in action and composition to the soluble true toxins; in fact, there is evidence to indicate the contrary. It is true that some bacteria, such as the dysentery bacillus, cholera vibrio, and a few other microorganisms that produce little or no soluble toxin, may be ground up so that the bacterial cells are mechanically ruptured, thus liberating the endotoxin. It is doubtful whether the so-called "endotoxins" exist as such in the bacterial cells, or whether they are poisons formed by the methods of extraction. The existence of endotoxin is an assumption based on scant experimental evidence. In some cases of so-called endotoxic action the reaction of anaphylaxis appears to be the best explanation.

## STANDARDIZATION OF ANTITOXIC SERA

The method of measuring the strength of diphtheria and tetanus antitoxins is exceedingly accurate and satisfactory. The tests are physiological, that is, depend upon animal experimentation. Guinea-pigs are used because they are particularly susceptible to both tetanus and diphtheria toxins and react to these poisons so uniformly that they serve the purpose of an accurate analytical balance. In order to obtain precise results it is essential that all the conditions of the test be uniform. It is, therefore, advisable to follow the official methods, which have been prescribed in great detail. All antitoxic sera upon the American market

are standardized in accordance with the official unit dispensed by the federal government. This work is done in the Hygienic Laboratory of the Public Health Service.

**The Standardization of Diphtheria Antitoxin.**—The immunity unit for measuring the strength of diphtheria antitoxin may be defined as the neutralizing power possessed by an arbitrary quantity of diphtheria antitoxic serum kept under special conditions to prevent deterioration in an authorized laboratory.

From a theoretical viewpoint the unit may be defined as that quantity of diphtheria antitoxic serum which will just neutralize 200 minimal lethal doses of a pure poison. By a "pure" poison is understood one containing only *toxin* and no *toxoid*, *toxone*, or other substance capable of uniting with the antibodies.

The first definition may be compared to the platino-iridium bars kept under special conditions in Paris or Washington as the standard yard or meter. If all the meter bars or yardsticks were lost it would be difficult, if not impossible, to reproduce others having the exact lengths of the originals. These standard measures are, therefore, guarded against deterioration just as the standard antitoxic sera are preserved under strict conditions of light, heat, moisture, etc., in the Hygienic Laboratory of the Public Health Service at Washington. From time to time duplicates of this serum are made to guard against deterioration or accident to the original.

The second definition may be compared to the original conception of the meter, which was intended to be one ten-millionth of the quadrant of a great circle of the earth. Theoretically, therefore, if all the meter bars were lost this unit of measurement could be reproduced with approximate fidelity. In the same way it is theoretically possible to reproduce the diphtheria antitoxic unit in consideration of that fact that it has just 200 combining units.

The test by which the strength of antitoxin is measured is a physiological one, and depends upon the neutralization of the toxin by the antitoxin. This neutralization can only be determined by injecting the toxine-antitoxin mixtures into guinea-pigs and noting the results. The unit for measuring the strength of diphtheria antitoxin is a measure of physiologic strength, not of quantity.

In all the early work on this subject the toxine was used as a basis for measuring the strength of the antitoxin, but as the toxine is a much more complex substance than the antitoxin, and as it is less stable, accurate results were not possible. Ehrlich showed that the antitoxin under certain conditions was permanent both in power of chemically combining with and physiologically neutralizing the toxine. One antitoxin, however, cannot be compared with another antitoxin directly. This can only be done through the toxine.

From a practical standpoint, the following illustration of a test will give a clear conception as to how the unit of strength of a serum is determined.

*Example of a Test.*—It is first necessary to obtain our official yardstick. This may be done by applying to the Hygienic Laboratory in Washington, where the standard serum is kept in a dry, powdered form in vacuum tubes under the influence of pentaphosphoric acid in a cold place and carefully preserved from the light. This powder is dissolved, carefully tested, and sent to the applicant in a glycerinated solution. Each cubic centimeter of a certain dilution of this standard serum contains just 1 unit. Before, however, we can measure the potency of an antitoxic serum of unknown strength it is first necessary to standardize a toxine. This is done by mixing one unit of the standard antitoxic serum with varying quantities of the toxine, as shown in table below.

From this series we learned that one unit contains just sufficient antitoxin to neutralize 0.16 c. c. of the toxine. This is known as the  $L_0$  dose.<sup>28</sup> By the  $L_0$  dose, then, is meant that quantity of toxine which just neutralizes or saturates one immunity unit as shown at the necropsy done 48 hours after the subcutaneous injection of the mixture into the guinea-pig. The reaction at the site of inoculation at this examination must be hardly noticeable.

Mixtures of Antitoxic Serum and Toxine Injected Subcutaneously into Guinea-Pigs.	Result.
1 immunity unit + 0.14 c. c. toxine	No reaction.
“ “ + 0.15 “ “	No reaction.
“ “ + 0.16 “ “	Slight congestion at site of injection. [This is the $L_0$ dose.]
“ “ + 0.17 “ “	Apparent reaction at site of injection.
“ “ + 0.18 “ “	Injection and edema at site.
“ “ + 0.19 “ “	Injection and edema at site; late paralysis.
“ “ + 0.20 “ “	Sometimes death in 5 or 6 days, sometimes late paralysis.
“ “ + 0.21 “ “	Always causes acute death about the fourth day. [This is the $L_+$ dose.]
“ “ + 0.22 “ “	Acute death usually on second or third day.
“ “ + 0.23 “ “	Acute death on second day.

In the above illustration the  $L_+$  dose of this toxine is just 0.21 c. c. By the  $L_+$  dose is meant the smallest quantity of poison that will neutralize one immunity unit plus a quantity necessary to kill the animal

<sup>28</sup>  $L$  stands for Limit.  $L_0$  stands for the limit of no reaction, and  $L_+$  the limit of acute death.

on the fourth day. The  $L_+$  dose is the test dose which is used to determine the strength of our unknown antitoxic serum, as follows:

The $L_+$ (or Test Dose of Toxin) + Varying Amounts of Antitoxin Injected into Guinea-Pigs.						Results.
0.21 c. c. toxine	+	1/150	c. c. antitoxic serum			No effect.
" "	+	1/175	" "			No effect.
" "	+	1/200	" "			Late paralysis.
" "	+	1/225	" "			Late paralysis.
" "	+	1/250	" "			Dies 4th day.
" "	+	1/275	" "			Dies 3d day.
" "	+	1/300	" "			Dies 2d day.

From this series it is evident that 1/250 c. c. of the serum contains that amount of antitoxin which will neutralize the toxin in the test dose, leaving sufficient free poison to kill the animal on the fourth day. The serum, therefore, contains one antitoxic unit in 1/250 c. c. of serum. One c. c. of the serum would, therefore, contain 250 units.<sup>29</sup>

**Standardization of Tetanus Antitoxin.**—There are four methods of measuring the strength of tetanus antitoxin: (1) the German method described by Behring; (2) the French method described by Roux; (3) the Italian method after Tizzoni, and (4) the American method established by Rosenau and Anderson.<sup>30</sup> European standards are admitted to be unsatisfactory and for the most part not accurate. Further, they are complicated and difficult to carry out. The American method, which has been made the official government standard for this and other countries, commends itself for its simplicity, directness, and precision.

The tetanus antitoxic unit is based upon the neutralizing value of an arbitrary quantity of antitoxic serum preserved under special conditions to prevent deterioration in the Hygienic Laboratory of the Public Health Service. This arbitrary quantity now contains ten times the amount of tetanus antitoxin necessary to neutralize somewhat less than 100 minimal lethal doses of a standard toxine for a 350-gram guinea-pig. That is, 0.1 of a unit mixed with 100 minimal lethal doses of the standard toxine contains just enough free poison in the mixture to kill the guinea-pig in four days after subcutaneous injection.

The official definition of a tetanus antitoxic unit is the following: The immunity unit for measuring the strength of tetanus antitoxin

<sup>29</sup> For the details for carrying out these tests the reader is referred to the *Hygienic Laboratory Bulletin No. 21* upon "The Immunity Unit for Standardizing Diphtheria Antitoxin," by M. J. Rosenau, which contains the official description and details of the process and its theoretical considerations.

<sup>30</sup> *Hygienic Laboratory Bulletin No. 43*, P. H. & M. H. Service, Washington, March, 1908.

shall be ten times the least quantity of antitetanic serum necessary to save the life of a 350-gram guinea-pig for 96 hours against the official dose of a standard toxine furnished by the Hygienic Laboratory of the Public Health and Marine Hospital Service.

The standardization of tetanus antitoxin does not differ radically from the standardization of diphtheria antitoxin. The toxins and antitoxins are mixed and the mixture injected into guinea-pigs. While, however, the unit is based upon the neutralizing value of an arbitrary quantity of antitoxic serum, the antitoxin is not issued for a basis of comparison, as in the case of diphtheria. A stable precipitated toxine, the test dose of which has been carefully determined, is issued to other laboratories for the purpose of testing.

The value of an unknown serum is measured directly from this standard precipitated toxine, the  $L_+$  or test dose of which is stated. The  $L_+$  or test dose of the particular toxine now dispensed by the government contains just 100 minimal lethal doses for a 350-gram guinea-pig. This particular toxine is very stable and has not changed appreciably in eight years. As soon as it alters or is exhausted the next toxine that will be issued may contain more or less than 100 minimal lethal doses, but the test dose will contain precisely the same neutralizing power.

The tetanus antitoxic unit may be better understood from an example of a test.

*An Example of a Test.*—Carefully tare a weighing bottle, then add approximately 20 to 50 mg. of the dried poison. Again carefully weigh. Dissolve the toxine in the weighing bottle with salt solution (0.85) in the proportion of 0.1 gram of the dried poison to 166.66 c. c. of the salt solution. This proportion is used for the reason that each cubic centimeter of this solution will represent 0.0006 gm. of the original dried poison (= 100 MLD's). This proportion is taken because it is very convenient in measuring out the test dose, which represents 1 c. c. of the solution. Thus:

$$\begin{array}{r}
 44.5692 \text{ gm., bottle + toxine.} \\
 44.5300 \text{ gm., bottle.} \\
 \hline
 .0392 \text{ gm., toxine.} \\
 0.1 \text{ gm. : } 166.66 \text{ c. c. : : } 0.0392 : x. \\
 x = 65.33 \text{ c. c.}
 \end{array}$$

In other words, if the quantity of toxine placed in the weighing bottle should weigh, as in this instance, just 0.0392 gm., carefully deliver from an accurately graduated burette just 65.33 c. c. salt solution into the weighing bottle; and, as before stated, each cubic centimeter of this solution will be the  $L_+$  or test dose.

Now dilute the serum of unknown value in accordance with the table

of dilutions, and mix aliquot parts of the serum with the test dose of toxine, as follows:

No. of guinea-pig	Weight of guinea-pig (grams)	Subcutaneous injection of a mixture of—		Time of death
		Toxine (test dose)	Antitoxin	
		<i>Gram.</i>	<i>c. c.</i>	
1.....	350	0.0006	0.001	2 days, 4 hours.
2.....	350	.0006	.0015	4 days, 1 hour.
3.....	350	.0006	.002	Symptoms.
4.....	350	.0006	.0025	Slight symptoms.
5.....	350	.0006	.003	No symptoms.

According to this series the guinea-pig which received the mixture containing 0.0015 c. c. of the serum died in four days and one hour. Therefore, 0.0015 c. c. of the serum contains one-tenth of an immunity unit, as the unit has been defined as ten times the least amount of anti-tetanic serum necessary to save the life of a 350-gram guinea-pig 96 hours against the official test dose. This serum would, therefore, contain just 66 units per c. c.

In order to obtain reliable and comparable results, it is necessary to take into account all the factors concerned—the composition of the poisons, their concentration, the diluting fluid, length of time the mixtures are allowed to stand, the site of inoculation, etc., in accordance with directions in the official methods.

## PHAGOCYTOSIS

Metchnikoff gave us the first physical explanation of immunity through his brilliant studies upon phagocytosis. Metchnikoff was a biologist, and as a result of his stimulating observations upon the phagocytes in all the orders of the animal kingdom he contributed much to our knowledge, not alone of immunity, but to our fundamental knowledge of nutrition and inflammation. The ingenuity and fertility of his views caused a flood of work from others upon these basic subjects in medical biology.

Phagocytosis is a process common to all cells having amebic motion and also to some fixed cells. A phagocyte is any cell capable of absorbing particulate matter into its substance. The process is best seen with an ameba under the microscope.

For a clear understanding of phagocytosis it is necessary to consider three phases of the process: (1) the approach, (2) the engulfment, and (3) the digestion.

The *approach* or *chemotaxis* is a phenomenon which is displayed by almost all motile, unicellular organisms, whether animal or vegetable, as well as by the leukocytes. It manifests itself by a movement of the unicellular organism or the phagocytic cell toward the particle and seems to be a response to a chemical stimulus. Chemotaxis is said to be *positive* when the leukocytes are quickly and energetically attracted to a substance, and *negative* when this attraction is lacking. There is considerable doubt whether there is true negative chemotaxis in the sense of repulsion. The degree of chemotaxis possessed by any substance may readily be determined by placing it in a capillary tube closed at one end and then inserting the open end of the tube into the tissue of an animal or into a fluid containing active phagocytes. If the substance has positive chemotactic power the phagocytes soon approach the free end of the capillary tube, which they enter; if the substance has negative chemotactic power the phagocytes are not attracted and do not enter the capillary tube. As Emery points out, the leukocytes are in many cases attracted into an infected area to their own undoing, and it must not be forgotten that "even in inflammatory processes which are mild in nature and favorable in result the number of leukocytes which may be killed in the conflict is enormous. The leukocytes are not independent protozoa inhabiting the blood and tissues, but an integral part of the organism. It is to the advantage of the latter that the former should be attracted at once to the seat of invasion, and hence the processes of evolution have led to the development of this function in the nomadic cells of the body. These are extraordinarily susceptible to chemotactic influences. They seem to be attracted by any deviation from the normal situation of the tissues and fluids—a slight injury, a hemorrhage, the presence of a poison, or a foreign body of any sort, or any dead or useless tissue—and the leukocytes are immediately attracted into the area affected. The more we regard the process the more we must regard it as one of the most exquisite examples of means to ends met with in the animal economy."

The *engulfment* of the bacteria may readily be studied in amebae in their free living stage. The protoplasm of the ameba is thrown out in the form of pseudopodia; these encircle the particle, which soon appears within the substance of the ameba. The engulfment of particles by the leukocytes and other cells is precisely the same.

The *digestion* within the cell is entirely comparable to gastric digestion in higher animals. It is now known that active proteolytic ferments dissolve the albuminous particles, and that this takes place in an acid medium may be demonstrated by the use of delicate indicators, such as neutral red.

The phagocytes may take up and digest either live or dead bacteria; they are not simply scavengers. They engulf particles of all kinds, both

organic and inorganic. Thus, in anthracosis the particles of coal are mainly carried and contained in the phagocytic cells. The phagocytes engulf and dispose of malarial pigment, the granules of pigment left after a hemorrhage, and other foreign particles in the body. Phagocytes are also enabled to absorb colloidal substances and fluids as well as particulate matter. They are enabled to dispose of a comparatively large mass by removing it piecemeal. Thus, the "core" of a boil is gradually removed, mainly by the phagocytes. Catgut and silk ligatures are similarly removed; the absorption of the tadpole's tail is disposed of through the same process.

Metchnikoff divided the phagocytes into free and fixed, macrophages and microphages.

The free phagocytes are the leukocytes, lymphocytes, and other blood cells, as the myelocytes from the bone marrow. The fixed phagocytes are the connective tissue cells and endothelial cells. The free phagocytes, according to Metchnikoff, play the more important rôle.

The microphages, or microcytes, are the mononuclear leukocytes, the polymorphonuclear leukocytes, and the wandering connective tissue cells. The macrophages, or macrocytes, are the large lymphocytes, the mononuclear pulp cells of the spleen and bone marrow, endothelial cells of the large vessels, and Kupfer's stellate cells of the liver. The microphages play an active part in all acute infections. They are the first to come in the field and for the most part are vegetarians, that is, they take up bacteria especially. The macrophages, on the other hand, are carnivorous, engulfing other cells and protozoön parasites, and are especially concerned in chronic inflammations, such as tuberculosis and leprosy, rather than in the acute processes. These distinctions between the free and fixed phagocytes, the microphages and macrophages, are entirely arbitrary. All the leukocytes have the power of phagocytosis, though in varying degree. This is readily seen in an opsonic preparation or in an examination of a smear of gonorrheal pus, when some of the polymorphonuclear leukocytes will be loaded with the cocci while others contain few or none. The small phagocytes (microcytes) are able to engulf protozoa and animal cells as well as bacteria.

Metchnikoff has insisted since the beginning of his studies upon phagocytosis that this process plays an important, if not the sole, rôle in immunity. He conceives that a true battle takes place between the cells and the invading germs. When phagocytosis is active and successful, immunity is the result. If phagocytosis is absent, or the phagocytes are unsuccessful, the result is susceptibility instead of immunity. Metchnikoff first studied the protective power of the phagocytes in a fresh water crustacean, the daphnia, which, from its transparency and small size, is a very suitable creature for observation. He found that the daphnia is subject to a disease due to the invasion of its body cavity by

the spores of a yeast (*Monospora*), and that if these spores gain access in large numbers they multiply, form into mature organisms, and finally kill their host. When, however, a few spores gain access he found the leukocytes of the daphnia approach them, form a wall around them, and finally digest and destroy them. It is obvious, therefore, that the immunity of the daphnia to this infection depends upon the activity of its leukocytes. Analogous instances are found in many other animals, including man. In the streptococcus infections particularly Metchnikoff believed their virulence depended upon the absence of phagocytic action.

It soon became evident to Metchnikoff himself that the mechanism of immunity was a much more complicated process than could be accounted for simply by the number and physical activity of the phagocytes. The simple act of phagocytosis alone could not explain all the phenomena. It, therefore, became necessary to study the processes of digestion and the products of excretion of the phagocytes. It soon became evident that the digestive power of the phagocytes is a very powerful one, and substances usually deemed entirely insoluble may be gradually removed by their action. Metchnikoff considered two of these substances to be concerned in immunity: the microcytase and the macrocytase.

The *microcytase* is a ferment-like substance obtained from the microcytes. It is thermolabile and corresponds in all essential respects to the alexin of Buchner or the complement of Ehrlich.

The *macrocytase* is a thermostable substance obtained from the macrocytes. It is concerned with specific acquired immunity. The macrocyte fastens itself to the bacteria, hence was called by Metchnikoff the fixator. It is similar in all essential respects to the "substance sensibilitrice" of Bordet, or the amboceptor of Ehrlich.

Buchner, as well as most other unprejudiced students in immunology, takes the middle ground between the doctrines of the cellular theory represented by Metchnikoff and his school and the doctrines of the humoral theory represented by Ehrlich. It now seems quite evident that both the cells and the body fluids play an important rôle in the mechanism of immunity. It is also equally evident that the mechanism of immunity differs widely with different infections; in some phagocytosis plays a dominant part; in others it seems that the fluids of the body are chiefly concerned. It must not be forgotten that even where the fluids of the body are the chief actors the antibodies are probably in all cases derived from the cells. Just what cells—whether the fixed tissue cells or the free phagocytes—are chiefly concerned in the production of these antibodies is not quite clear.

All observers are agreed upon one fundamental thought, and that is, immunity is closely allied to the processes of cell nutrition. The receptors of Ehrlich are the mouths of the cells for food. The phago-

cytosis of Metchnikoff is primarily a mechanism by which cells possessing amebic motion obtain their food. Anaphylaxis, which offers another explanation of immunity to certain infections, deals with the fundamental problems of protein metabolism. It is, therefore, plain that any experimental research that gives a deeper insight into protein metabolism as well as the more direct researches in immunology has a fundamental bearing upon the prevention and cure of disease.

### OPSONINS

The name opsonin (*ὀψωνίω*, I cater for, I prepare) is given to substances which occur in the blood and which have the power of preparing bacteria and other cells for ingestion by the leukocytes. The opsonins combine with the bacteria and in that way prepare them for being taken up more easily by the phagocytic cells. In the absence of opsonins, phagocytosis does not take place, and their great importance is, therefore, at once manifest. There is now no doubt concerning the existence of these substances, and the brilliant work of Wright has stimulated a flood of researches which have thrown much light upon this chapter in immunology. According to Rhumbler, opsonic action merely shows the presence of something that affects the surface tension of the bacteria.

The opsonins are normally present in the blood or may be increased or diminished in amount by the injection of bacteria or appropriate antigen. The opsonins are specific, that is, the blood serum may contain opsonins which prepare staphylococci for the phagocytes, but may contain no suitable substance to prepare streptococci, tubercle bacilli, or some other microorganism. The opsonins are probably similar to the bacteriotropins; their chemical nature, however, in common with other antibodies, is not understood.

*Tropins* are simple antibodies, not affected by the usual inactivating temperature, 56° C. They act without the aid of complement. The opsonins are complex, containing thermolabile complement as well as a more stable body. They are inactivated at 56° C. for 30 minutes, or by standing at ordinary temperatures.

*The Opsonic Index.*—Sir Almroth Wright has modified Leishmann's method for measuring the opsonic power of the blood serum, but the method is somewhat complicated and gives variable results even in the hands of trained workers. It may be questioned whether any of the tests now in use are a true index of the amounts of opsonins in the serum, although they may be taken to indicate roughly the measure of their activity. The opsonic index has been especially used as a guide to vaccine therapy rather than in preventive medicine. If, however, we had a satisfactory and ready method by which the specific opsonins of the

blood could be measured so that deficiencies could be readily determined and strengthened, we would theoretically at least have a valuable addition to prophylaxis.

## LYSINS

Lysins are "substances" that have the power of disintegrating or dissolving cells or other organized structures. Those that dissolve bacteria are known as the *bacteriolysins*, those that dissolve red blood cells are called *hemolysins*, those that dissolve epithelial or other body cells are called *cytolysins* or cytotoxins. The lysins in themselves are not poisonous, but through their action they may liberate or generate toxic substances and thus play an important rôle not only in the pathogenesis of many infectious diseases and diseased states, but also in their cure and prevention.

Normally the blood possesses bactericidal properties, and it is believed that this is almost entirely due to its power of dissolving the bacterial cells.<sup>31</sup> The bacteriolytic property of normal blood serum is not specific, whereas the bacteriolysins induced through special processes by immunization are strictly specific. The fact that the blood has the power of resisting decomposition longer than other animal fluids was known to Hunter before the era of bacteriology. It was also early known that this property of the blood diminishes spontaneously after it was shed and could be destroyed by heat—about 55° C. The bacteriolytic substances in the blood were first studied by Buchner and Nuttall, who called them alexins. When it was discovered that the blood possesses marked powers of destroying bacteria the conclusion was naturally drawn that herein lies the explanation of immunity. It was soon learned, however, that, though the blood of certain animals may possess marked bactericidal properties, nevertheless they are very susceptible; and, further, that the power to kill bacteria is much more marked in the serum *in vitro*, than in the live circulating blood in the animal. Thus, according to Lubarsch, 16,000 virulent bacilli will kill a rabbit if injected intravenously; that is, the blood within the body has not the power of killing this number, yet 1 c. c. of fresh blood serum will destroy this number or even more in a test tube.

Rabbits are very susceptible to anthrax, although the blood serum of these animals possesses marked bactericidal properties *in vitro*, for the anthrax bacillus; on the other hand, the dog is very resistant to anthrax, despite the fact that its blood serum is very slightly bactericidal.

The bacteriolysins were discovered by Richard Pfeiffer<sup>32</sup> in his attempt actively to immunize animals against cholera by the injection

<sup>31</sup> Demonstrated by Nuttall, in 1888.

<sup>32</sup> *Zeit. f. Hyg.*, Vol. XVIII, and *Deutsche med. Wochen.*, 1896, pp. 97, 119.

of live cultures. He observed that the cholera organisms were disintegrated and dissolved in the peritoneal cavity of the immunized animals. This gave rise to what is now known as Pfeiffer's phenomenon, which, on account of its importance, must be considered.

**Pfeiffer's Phenomenon.**—Guinea-pigs are immunized by the subcutaneous injection of increasing doses of a cholera culture about once a week until they are able to withstand large amounts of a fresh virulent strain. This usually required at least three or four injections. Some of the live microorganisms are now injected into the peritoneal cavity of the immunized animal, and from time to time minute drops of this injected material with the peritoneal exudate are withdrawn by means of capillary tubes and examined under the microscope. It will be found that the bacteria previously actively motile soon lose their power of motion and die. They then become somewhat swollen and agglutinate into balls or clumps, which gradually become paler and paler. The disintegrating bacterial cells become granular and finally are completely dissolved in the peritoneal fluid. This process usually takes about twenty minutes, provided the animal has been sufficiently highly immunized. For a control, a like quantity of the cholera culture is injected into the peritoneal cavity of a normal guinea-pig. In this case the microorganisms are not immobilized, agglutinated, or dissolved. Further, the immunized animal remains unaffected while the control animal dies as a result of the infection. This reaction is specific, that is, a guinea-pig immunized against cholera will immobilize, agglutinate, and dissolve only the cholera vibrios; a guinea-pig immunized with typhoid will act upon typhoid and not upon cholera.

It was soon discovered by Bordet that this reaction takes place not only in the peritoneal cavity of the immunized animal, but will occur in the test tube when the peritoneal exudate or the blood serum of the immunized animal is mixed with the cholera organisms. It was through a study of this reaction that Pfeiffer and Kolle and later Gruber and then Widal discovered and described the ability of blood serum to clump or agglutinate bacteria. It seems evident that this power of the blood serum or the peritoneal exudate of the immunized guinea-pig is an important factor in the mechanism of its immunity.

**Nature of Lysins.**—Bacteriolysins are absolutely distinct from anti-toxins and agglutinins. Even when these three substances coexist they may be distinguished one from another through appropriate tests. Nothing is known as to their chemical composition.

Any general statement concerning the thermal death point or other characters of the lysins must be misleading, from the fact that we now know that lytic action is always due to a combination of two substances; one stable, the other unstable; one readily destroyed by heat, the other quite resistant to heat. This important observation was made by Bordet,

who was the first to show that two substances are necessary for the phenomenon of bacteriolysis. He considered that one of these substances sensitized the bacteria, and, therefore, called it the "substance sensibilisatrice"; this substance is thermostable. The other substance, which is thermolabile, he continued to call alexin. Bordet found that all the essential features of bacteriolysis could be reproduced exactly if red blood corpuscles were substituted for the bacteria. It was this analogy between bacteriolysis and hemolysis that led Ehrlich to an investigation of the latter phenomenon, and his researches led to further light upon the subject. Ehrlich introduced new names for the substances which Bordet had shown to be necessary for the phenomenon, and applied his side-chain theory to explain the reaction.

Many names have been given to the two substances which take part in lysis. The thermostable substance has been called substance sensibilisatrice, or simply sensibilatrice, immune body, amboceptor, fixator, intermediary body, interbody, philocytase, immunisin, desmon, copula and preparator; while the thermolabile substance has been called the alexin, complement, addiment, and cytase. We shall speak of the first as the *immune body* and the second as the *complement*.

One of the remarkable facts connected with the phenomenon of the lytic poisons is that the poison itself (complement) is normally present in the blood. This substance is a fragile "body," readily destroyed at a moderate temperature—55° C. It disappears spontaneously from the serum when kept for a few days; it is destroyed by acids and alkalis and is not specific in its action. Complement appears to be formed by the breaking down of the leukocytes, which accounts for the fact that blood serum after clotting is much more potent than the whole blood; further, complement is absent from fluids containing no leukocytes, such as the aqueous humor. Complement exists in blood while it is physiologically alive. It may not be a "substance" in the chemical sense, but a state of colloidal dispersion of the proteins of the serum.

According to Ehrlich, the immune body has two combining affinities, and, therefore, he called it the amboceptor. It unites on the one hand with the complement and on the other with the receptor of the cell. Bordet, however, considers that the cell unites directly but separately with both the complement and the immune body. The immune body is stable and specific; it is more stable than the agglutinins or even the anti-toxins. It is not injured by heating to 60° C., it is weakened at 70° C., and finally destroyed by prolonged exposure at this temperature. It is called the immune body because, according to Ehrlich's views, immunity can only be obtained through it on account of its specific reaction.

In bacteriolytic immunity it is the immune body rather than the complement that is increased.

Just what service the lysins are in the mechanism of immunity is

not clear. Recent studies indicate that they may at times be harmful as well as useful. Thus, by dissolving the bacterial cell they have the power of releasing "endotoxins."

The studies upon anaphylaxis have thrown collateral light upon the probable action of the bacteriolysins in the pathogenesis, cure, and prevention of some infections. When the bacteria are dissolved within the body the protein matter which they contain is set free. This may not be poisonous in itself, that is, may not have any of the properties ordinarily attributed to the endotoxins. This foreign bacterial protein, however, may sensitize the organism so that the second time the protein is liberated it may cause a reaction which may account for some of the pathogenic effects and symptoms of the disease.

Buxton and Coleman explain the pathogenesis of typhoid fever as largely due to a solution of the typhoid bacilli within the body, and it is probable that in pneumonia and other infections a like action takes place. An organism that has once reacted to a particular bacterium remains immune so long as it possesses an altered power of reaction, when brought in association with the microorganism in question. Immunity in this sense is an example of allergie and is discussed more in detail under anaphylaxis.

### HEMOLYSINS

Hemolysins are substances that lake the blood; that is, they dissolve the hemoglobin from the red blood corpuscle and set it free in solution. A certain part of the stroma of the red corpuscle is also destroyed in complete hemolysis. Some of the hemolysins are specific and others are not. Thus, distilled water will dissolve the hemoglobin from the red corpuscles of almost all animals. Other known non-specific hemolytic substances are various alkalies and acids; plant poisons, such as ricin and abrin; bacterial poisons, such as tetanolysin and staphylolysin; and animal poisons, such as snake venom, scorpion venom, etc. The specific hemolysins are obtained by treating (i. e., immunizing) one animal species with the blood corpuscles of another. For example, the blood corpuscles of a guinea-pig are injected into a rabbit. After several such injections the blood serum of the rabbit will contain hemolytic substances for the guinea-pig's corpuscles. The corpuscles used for immunization are obtained by drawing the blood of the animal into isotonic salt solution (0.85 per cent.) containing about 1 per cent. of sodium citrate, which prevents coagulation. The citrated blood is then centrifugalized, the supernatant fluid drawn off and replaced with isotonic salt solution. This process is repeated three or four times and is known as washing the corpuscles. The object is to remove all trace of serum containing complement and other substances. If this is not done the results will be unnecessarily complicated and misleading. The washed cor-

puscles are injected into the peritoneal cavity about once a week or ten days until the blood contains the desired hemolytic action. When this point is reached can only be determined by withdrawing small quantities of the blood and testing it.

Hemolytic tests are made by adding together the complement and the immune bodies. The corpuscles are obtained as above described, washed three or four times, and suspended in isotonic salt solution, so that they are present in the proportion of about 5 to 10 per cent. by volume of the salt solution. One c. c. of this suspension is placed in a small test tube. To this is then added the immune body contained in the serum of the animal that had been injected with the corpuscles. This immune serum is first heated to 55° or 56° C. for half an hour in order to destroy the complement. This degree of heat does not destroy the immune body.<sup>33</sup> Uniform amounts of the complement are obtained by adding a definite quantity (0.2 of a c. c.) of fresh serum to each test tube. Each test tube then contains a uniform quantity of the corpuscles to be tested, a uniform quantity of complement in the fresh serum, and a variable quantity of heated immune serum containing the immune body. In most cases normal saline solution is added to bring the whole up to a definite volume—say 5 c. c.

These mixtures are now incubated at 37° C. for two hours, being stirred or shaken once or twice in the meantime. The test tubes are now removed and placed in a vertical position in the ice chest from 12 to 24 hours and then examined. If no hemolysis has taken place the supernatant fluid will be untinged and the corpuscles will have settled in a distinct layer at the bottom. If there is complete hemolysis the fluid will be deeply and uniformly colored and there will be no sediment or only a minute deposit of stromata. If the reaction is partial, the fluid will be less deeply colored and there will be more or less of a deposit of undissolved corpuscles. It must be remembered that many bacteria produce hemolysis and that, if the mixtures of corpuscles and sera be incubated for long periods, fallacies may arise from such contaminations.

### CYTOTOXINS

If instead of red blood cells an animal is treated with the body cells or glandular cells of another species, it develops the power to dissolve the cells in question. This power is contained in the blood serum and is brought about by substances known as cytotoxins, which are entirely similar to the bacteriolysins, the hemolysins, and other lytic substances. Cytotoxins have been obtained with the spleen (leukocidin), with the sperm (spermotoxin), liver cells (hepatotoxin), kidney cells (nephrotoxin), gastric mucosa (gastrotoxin), placental tissue (syncy-

<sup>33</sup> This degree of heat weakens the immune body about 25 to 30 per cent.

tiolysin or placentolysin), prostatic tissue (prostatolysin), brain (neurotoxin), and other organs and tissues. When the cytotoxins were discovered they aroused great enthusiasm in the hope that it would now be possible to dissolve and destroy such foreign cells as cancer and other tumors and pathological processes in which it is desirable to get rid of certain cellular elements. The practical results have been exceedingly disappointing, as further investigations have shown that these cytotoxins are exceedingly weak and, further, are not very specific.

### THE BORDET-GENGOU PHENOMENON—FIXATION OF COMPLEMENT

Bordet and Gengou<sup>34</sup> found that bacteria and also red blood cells could be "sensitized" by placing them in heated immune serum. The immune serum is heated to 55° or 56° C. in order to destroy the complement, leaving only the thermostable "substance sensibilisatrice" which unites with the bacteria or the red blood cells, and thus prepares or sensitizes them to the action of the complement. If, now, these sensitized bacteria or red corpuscles are added to fresh serum, all the complement contained in the fresh serum is removed or fixed so that the fluid will no longer dissolve bacteria or cells. These facts are of very great importance, and upon them are based the Wassermann reaction for syphilis and other practical applications in immunology. The complement fixation test is also used in the diagnosis of gonococcus infection, glanders (page 399), streptococcus infections, pertussis, meningitis, typhoid fever, and other infections.

The reaction of fixation based upon the work of Bordet and Gengou has many useful practical applications in addition to the Wassermann reaction for the diagnosis of syphilis. If either the antigen or the antibody are unknown, their presence may be determined through the reaction of fixation, because it is strictly specific. The problem is something like the theorem in geometry with the triangle; two sides and an angle of a triangle being known, the other side and angles may be determined.

The *antigen* is any substance which, when injected into a suitable animal, has the power of generating an antibody. Practically all pathogenic bacteria and pathogenic protozoa act as antigens; many albuminous bodies, such as the venoms, the enzymes, and bland proteins, may also act as antigens. As the reaction is specific, it is possible to determine whether a particular microörganism is the true cause of a disease or not.

<sup>34</sup> Bordet: *Ann. de l'Inst. Pasteur*, Vol. XIV, 1900, p. 257; Vol. XV, 1901, p. 289.

Gengou: *Ann. de l'Inst. Pasteur*, Vol. XVI, 1902, p. 734.

Bordet and Gengou: *Compte rendu Acad.*, Vol. CXXXVII, p. 351.

Thus, Bordet was enabled to satisfy himself that the bacillus which he isolated during the early stages of whooping-cough was the true cause of that disease, as it gave the reaction of fixation with a specific antibody. On the other hand, if the antigen is known, the diagnosis may be made through the reaction of fixation, as in the case of syphilis and the Wassermann reaction. Complement fixation is used to show generic differences between bacteria, whereas agglutinins at most show specific differences.

The **Wassermann reaction** for syphilis is a special method of application of the Bordet-Gengou phenomenon.

The following is a brief description of the Wassermann reaction as carried out for the Massachusetts State Department of Health, by Dr. W. A. Hinton, under my direction.

Two antigens are used: one is an alcoholic extract prepared from human heart muscle and half saturated with cholesterol at 17° C., the other is prepared in like manner from guinea-pig hearts. Each of these antigens is diluted with 0.85 per cent. salt solution before testing, in the proportion of 4 parts of the antigen extract to 16 parts of 0.85 per cent. salt solution. The amount to be used—the dosage—is carefully determined by testing each antigen against a large number of known positive and known negative specimens of blood. Any antigen which gives a positive reaction with a known negative specimen of blood ("false positive") is unsuitable for testing and should be rejected. Further, it is unsafe to employ an antigen when twice its dosage inhibits hemolysis when incubated for 1 hour with "the hemolytic system" consisting of complement, and the hemolytic mixture.<sup>35</sup> (See Antigen Control in table on Wassermann Test.) Usually 0.1 c. c. to 0.2 c. c. of the diluted antigen is used. Lecithin and other lipoidal substances may also act as antigen.<sup>36</sup>

Syphilitic antibody in the patient's serum to be tested is the unknown quantity. This serum is heated in a water bath at 55° C. for 30 minutes to destroy its complement. One-tenth cubic centimeter of the patient's serum is used in *the test* and 0.2 cubic centimeter is used for *the serum control*. The serum control indicates the presence or absence of inhibiting (anticomplementary) substance other than specific antibodies.

The *complement* is contained in the serum of freshly drawn guinea-pig's blood which has been kept at 37° C. for one to two hours. A 10 per cent. solution of this serum in salt solution constitutes the complement. The amount used in the test is twice the minimum necessary to hemolyze a definite quantity of sensitized cells. Usually this is from 0.4 to 0.5 c. c. of the complement.

*Washed corpuscles* are prepared from freshly obtained defibrinated

<sup>35</sup> Also known as sensitized red blood cells.

<sup>36</sup> In routine examinations upon a large number of specimens it is better to test all specimens first with a cholesterolized alcoholic extract prepared from guinea-pig hearts (this antigen being more sensitive to syphilitic antibody), and then retest the positives with the same antigen and also with an antigen prepared from a cholesterolized alcoholic extract of human heart muscle.

## WASSERMANN TEST

Number of tube	Antigen	Antibody	Complement	Saline Solution 0.85%	Incubate 40 minutes in water bath at 37° C.		Result
					Hemolytic Mixture 5% suspension of sheep's corpuscles + heated rabbit's immune serum (ambocceptor)	Incubate for 1 hour in water bath at 37° C. Note results immediately and again after having kept in ice box for 12 to 14 hours.	
Antigen Control	0.2 c. c.	0.0 c. c.	0.5 c. c.	0.8 c. c.	1.0 c. c.		Hemolysis should be complete
Serum Control	0.0	0.2	0.5	0.8	1.0		Hemolysis should be complete
Serum Test	0.1	0.1	0.5	0.8	1.0		No Hemolysis = syphilitic antibody in patient's serum (Positive) Hemolysis = absence of syphilitic antibody in patient's serum (Negative) Partial Hemolysis = Doubtful result
Diagrammatic Representation of Positive and Negative Test	Antigen	Syphilitic Antibody	Complement		Hemolytic Mixture		Hemolysis absent = Positive
							
		Syphilitic Antibody (Absent)					Hemolysis present = Negative
							

For routine tests the positive serum of a known syphilitic, the negative serum of a non-syphilitic and each of the serums (or spinal fluids) to be tested are set up according to tubes No. II and No. III, together with one antigen control according to tube No. I.

\* The dilution is made so that 0.1 c. c. contains one-half the maximum amount or less than one-half the maximum amount which does not inhibit hemolysis. A carefully standardized alcoholic extract of human heart muscle, half-saturated with cholesterol, usually gives a superior antigen. (See text.)

\*\* Use five times the quantity of spinal fluid not heated.

† Five-tenths cubic centimeter contains two units, as determined against the hemolytic mixture.

‡ The amount of immune rabbit's serum in each c. c. of this mixture is twice that necessary to hemolyze 0.5 c. c. of a 5% suspension of sheep's cells in the presence of 0.5 c. c. of 10% complement.

sheep's blood. In order to free the corpuscles of serum, the blood is washed three times with from four to five volumes of physiological salt solution at each washing. Finally the volume of cells and salt solution is made equal to the volume of defibrinated blood originally used. Such a suspension is called washed sheep's corpuscles from which the 5 per cent. suspension for the test is prepared.

*Immune rabbit's serum* is prepared by injecting washed sheep's corpuscles into the peritoneal cavity of a rabbit at three-day intervals, namely, first injection, 7 c. c.; second, 14 c. c.; third, 21 c. c.; and finally, 28 c. c. The rabbit is bled on the 9th or 10th day after the last injection and the clear serum obtained from its blood is heated in a water bath at 55° C. for one-half hour to destroy complement. This heated rabbit's serum contains the amboceptor and is diluted with 0.85 per cent. salt solution, so that 0.25 c. c. will hemolyze 0.5 c. c. of a 5 per cent. suspension of sheep's corpuscles. In the test 0.5 c. c. of the diluted amboceptor is used. A small quantity of the rabbit's serum is freshly diluted for each day's test.

The *hemolytic mixture, or sensitized cells*, consists of equal parts of a 5 per cent. suspension of washed sheep's corpuscles and the diluted amboceptor which have been incubated together in a water bath at 37° C. for one-half hour completely to sensitize the red corpuscles. One c. c. of sensitized cells is used in the test.

*The Test.*—Mix the patient's serum or spinal fluid with the antigen and the complement, according to the table on page 582. The tubes are well shaken and the whole is incubated at 37° C. for 40 minutes. At the end of this time all of the complement has been fixed in those tubes which contain syphilitic antibody, antigen and complement. Finally, 1 c. c. of sensitized cells is added to each tube and the whole again incubated at 37° C. for one hour. The results of the Wassermann test are then read.

The absence of hemolysis indicates the presence of syphilitic antibody in the patient's serum, and therefore a positive reaction. The presence of hemolysis indicates the absence of syphilitic antibody in the patient's serum, and therefore a negative reaction. Partial hemolysis signifies a doubtful reaction. It is advisable to test several specimens from such a case, and to interpret a persistently or predominatingly doubtful reaction as indicative of a syphilitic infection.

## THE NEISSER-WECHSBERG PHENOMENON OR DEVIATION OF THE COMPLEMENT

Neisser and Wechsberg in 1901<sup>37</sup> found that, although the addition of a small amount of immune serum renders normal serum more bac-

<sup>37</sup> *Munch. med. Wochenschr.*, 1901, No. 18.

tericidal or increases its power of protection, a greater addition robs it of most, and sometimes of all, of its bactericidal power. In other words, the solvent effect of the immune body on cells or bacteria in the presence of complement diminishes as an excess of the immune body is added. This particular action is explained by Neisser and Wechsberg as due to a locking up or deviation (*Ablenkung*) of the complement which is brought about by an excess of the immune body. The

DIAGRAM ILLUSTRATING DEVIATION OF COMPLEMENT (Neisser Wechsberg Phenomenon)					
TEST	A BACTERIA Same number in each Test.	B COMPLEMENT Same amount in each Test	C AMBOCEPTOR Variable amount of Immune Serum in each Test	COMBINE A B and C	RESULT
I		vvvvvv	~		Few or no bacteria killed.
II		vvvvvv	~~~~~		All bacteria killed.
III		vvvvvv	~~~~~ ~~~~~		Few or no bacteria killed because the Complement is deviated by the excess of Amboceptor.

FIG. 61.

phenomenon is better understood from a study of an example given by Neisser:

(1) Bacteria+1 unit immune serum<sup>38</sup> +complement=little or no destruction of the bacteria.

(2) Bacteria+5 units immune serum+complement=complete destruction of the bacteria.

(3) Bacteria+10 units immune serum+complement=no destruction of the bacteria.

<sup>38</sup> Containing amboceptor.

In the above experiment it is necessary that the number of bacteria and the amount of complement shall remain practically the same in all three tests. The immune serum is the only factor that should vary.

In (1), few or no bacteria are killed because there are not enough immune bodies (amboceptors) to unite the complement to the bacteria.

In (2), the proper proportion of amboceptors and complement occurs so that all the bacteria are killed.

In (3), few or no bacteria are killed for the reason that the complement is deviated by the excess of amboceptors.

The action, therefore, while specific, is strictly quantitative, depending upon the amount of amboceptors present. This explains why an immune serum may be effective in certain infections if the proper dose is used, but large amounts of immune serum may be ineffective in controlling the course of the disease.

**Isohemolysins** have the property of destroying the red blood cells of the same species. They occur naturally in certain animals, principally in the horse and in man. They may also be produced experimentally in certain animals, as in goats, by the injection of the blood of other goats. There is further the possibility that *autohemolysins* may be produced which destroy the blood cells of the individual himself. These have not been produced artificially, but are said to occur in paroxysms of hemoglobinuria. The subject of *isohemolysins* is of importance in transfusion.

## PRECIPITINS

Another class of immune bodies known as the precipitins may readily be produced in the blood serum of animals by the injection of bacteria or albuminous substances having this antigenic property. The precipitating action of immune sera was discovered by R. Kraus in 1897. When the clear antiserum is added to the clear antigen in solution, the mixture of the two fluids becomes opalescent, then opaque from the formation of a precipitate, and after a time this settles to the bottom of the test tube, leaving a clear supernatant fluid. One theory of precipitins is that the precipitate consists of a combination of two substances, one of which is present in the immune serum and the other in the antigen. A more likely theory is that the precipitate is composed of the globulin of the immune serum which comes down due to a change in the electric charge. This insoluble precipitate is known as the *precipitum*. The substance in the antigen is known as the precipitable substance or *precipitinogen*, and the substance in the antiserum is called the *precipitin*. Precipitums are doubtless formed within as well as without the body when proper conditions of antibody and antigen are

present. The reaction, however, may not be massive enough to cause a visible precipitum.

The precipitins are quite analogous to the agglutinins, and from the standpoint of physical chemistry are often classified with them. It is now known that proteins do not form true solutions, but molecular or colloidal suspensions. The effect of the addition of a precipitin is to cause the agglutination of particles. According to Emery, the laws which govern the action of the precipitins and agglutinins are entirely similar, and theoretically it would probably be more accurate to consider them under one head. The practical applications of the two classes of antibodies are, however, very different, and it is more convenient to treat them as separate phenomena.

Precipitins as well as agglutinins probably act by change of surface tension and alteration of the electric charge of the particles.

The bacterial precipitins were those first discovered. Kraus added some typhoid serum to a filtered culture of typhoid bacilli and obtained a precipitate when the two clear solutions were brought together. The same happens with cultures of cholera, plague, and other bacteria with corresponding antiserum. Certain bacteria, however, do not produce a precipitable substance. This is notably the case with diphtheria. Thus, when diphtheria antitoxin is added to diphtheria toxin, no visible reaction takes place.

Tsistowitch in 1899 found that precipitins may be produced by injecting albuminous substances into suitable animals. Thus, if rabbits are injected with horse serum or with eel's blood, the blood serum of the treated rabbit will precipitate the blood serum of the horse or the eel's blood respectively. This reaction is used in forensic medicine for the recognition of blood stains, which will presently be discussed. The chemical nature of the precipitins is not known. They come down with the globulins. In the terms of the side-chain theory they contain two groups, one a thermostable haptophore or combining group, the other a thermolabile functioning group. Precipitins are destroyed by heat ( $60^{\circ}$ - $70^{\circ}$  C.), light, moisture, and other external influences about as readily as the agglutinins. Precipitating sera should, therefore, be kept in a dry state, in a cool place, and preserved from light. A proprecipitoid zone entirely analogous to the proagglutinoid zone is observed under certain conditions. Precipitins, like agglutinins, act more quickly at the body temperature and require the presence of certain salts for their action. According to Friedemann, the amount of precipitum formed depends on the quantity of the salts present.

The relation of precipitins to immunity is not entirely clear. There is a strong suspicion that, like all antibodies, they play some part in the mechanism of immunity in certain infections, but just what part is obscure. It is quite evident that the presence of precipitins in the

blood must have valuable protective properties against the poisons of certain infections. The immunity in this case would be due to the throwing out of "solution" of the poison, thus rendering it insoluble and inactive.

Nuttall in his "Blood Relationship" made a very careful study of the question of specificity of the precipitins.

He showed that the reaction of the precipitins, like the reaction of other similar antibodies, is relatively specific or quantitatively specific. If the antiserum is powerful enough it will react with all the bloods of animals in the same great division of the animal kingdom. Thus, a strong antihuman serum, that is, a serum obtained by injecting human blood into rabbits, will give a precipitate when this rabbit serum and human serum are brought together; it will also react with apes, monkeys, etc., but not in such high dilutions, and a slight trace of precipitum appears after a long period even when mixed with the serum of more remote mammalia, but no precipitate occurs with the blood of birds, fishes, etc. A quite similar relationship holds with lactosera and with the precipitating sera for muscle proteids; the antisera for egg proteids are apparently less specific. Precipitins, then, are not specific as regards the animal species from which they are derived, but possess that partial specificity seen in the cytotoxins and in the group reaction of the agglutinins. According to Emery, they are specific as regards the antibodies which bring them into existence, irrespective of the source from which the antigen is derived. For medico-legal purposes the specificity of the reaction may be considered satisfactory, provided the tests are made quantitatively, in which case the reaction is both specific and delicate. In fact, the delicacy of the reaction is truly astonishing. Thus, Ascoli obtained an anti-egg albumin serum which gave a precipitate with 1-1,000,000 dilution of egg albumin; and Stern an antihuman serum which reacted with serum at a dilution of 1-50,000. While these are extreme figures, it is not unusual to obtain precipitates in dilutions of 1-5,000.

The practical application of precipitins is limited. The test is especially used to differentiate types of pneumococci. It is also used to determine the presence and variety of bacterial substances in excretions, exudates and lesions. Thus, in lobar pneumonia considerable soluble products of the pneumococcus are found in the lungs, sputum, blood and urine. Precipitins are also of practical use in forensic medicine as a test for blood, meat and other products.

**Tests for Blood.**—In carrying out the precipitin tests for the recognition of blood stains, as suggested by Uhlenhuth and Wassermann, it is necessary first to obtain an antiserum. This is usually gained from rabbits, which are injected intravenously or intraperitoneally at intervals of three or four days with human serum. The human serum may readily be obtained by puncturing a vein at the bend of the elbow, or from the

placenta, or from a cadaver; pleuritic or ascitic fluid may also be used. The amount injected rises from 1 to 3 or 4 c. c. in the case of intravenous injections, or twice as much or even more into the peritoncum. The course of treatment lasts three or four months. A simpler method is to give larger doses up to 10 c. c. or more intraperitoneally at intervals of a week. The intervals should not be longer than this, for danger of complicating anaphylactic reactions. The blood may be drawn from a vein or the heart of the rabbit from time to time as needed, or the animal may be chloroformed and exsanguinated through the carotid artery, or as much blood as possible may be collected from the heart.

The blood to be tested is usually in the form of clots or stains, usually upon linen, or pistols, or other objects. These stains are macerated with normal saline solution or with 1 per cent. sodium hydrate. In the case of very old stains Zienka recommends the use of a strong solution of potassium cyanid which is subsequently neutralized with tartaric acid. The fluid is then examined with the microscope and tested spectroscopically to determine the presence of blood corpuscles and pigments, so as to be sure we are really dealing with blood. The solution is then filtered. In order to determine the approximate strength of the solution it is sufficient to bubble air through the fluid. A dilution of blood serum in the proportion of 1-1,000 will produce a stable foam. If a stable foam is not produced it indicates that the protein material has not actually passed into solution or is too dilute to be of service in the test. Three tests are made. In the first tube one part of the fluid under examination is mixed with two parts of the antiserum, the second contains the fluid alone, and the third antiserum plus normal saline solution. Further controls in which the antiserum is mixed with diluted serum from animals other than man may also be made. The tubes are then incubated at 37° C. and examined from time to time. A positive result is obtained if there is a precipitate in the first tube and not in the others. In case a precipitate is obtained further tests are then made with greater dilutions. With a powerful antiserum a reaction may usually be obtained in dilutions so high that evidence of the presence of proteids is barely obtainable by ordinary chemical means. The weak point in the method is that it is never possible to say exactly how much of the protein matter of the clot has been dissolved, and thus it is not possible to obtain precise quantitative results. With an unknown blood serum, unaltered, and in the fluid state the test can be carried out with almost complete certainty, but this is rarely if ever possible in medico-legal cases.

Another test for blood has been introduced by Neisser and Sachs and based on the Gengou reaction of fixation of the complement. The test is extraordinarily sensitive. Neisser and Sachs found that one-millionth part of a cubic centimeter of human serum is readily demon-

strable. The technic is complicated, and, according to Emery, it appears, moreover, that complement may be extracted in an altogether non-specific manner by substances other than the combination of antigen and antibody. Another serious objection is that a similar deviation of the complement may be brought about by means of sweat, so that if the reaction were obtained in a stain on body linen it would be of doubtful significance.

The precipitin reaction further finds practical application in determining the nature of meat, whether fresh, as in the case of beef suspected to be horse flesh, or prepared, as in sausages, etc. For these tests the antiserum is prepared by injecting rabbits with meat juices or an unheated watery extract of the meat, and the test is carried out on lines similar to those described above.

## AGGLUTININS

Agglutinins were definitely described in 1896 by Gruber and Durham, and a few days later by Pfeiffer and Kolle. Shortly thereafter Widal announced the fact that the blood serum of a typhoid patient will agglutinate the typhoid bacillus in high dilutions. The phenomenon of agglutination with special reference to typhoid fever is, therefore, often called the Widal reaction or the Gruber reaction.<sup>39</sup>

Agglutination consists in a clumping or grouping of the bacteria into clusters, just as though they were iron filings drawn about a magnetic point. Usually they are immobilized before they are drawn together into a clump or cluster. Theobald Smith has shown that the first phenomenon, the immobilization of bacteria, may be due to a *flagellar agglutinin*, and that the second phenomenon, the clumping, may be due to a *cellular agglutinin*.

The agglutination of bacteria apparently does little harm to them other than rendering them motionless, for they are not altered in appearance, viability, or virulence. Bacteria that have been agglutinated may again multiply and grow vigorously; in fact, agglutination may be an important source of error in counting the number of bacteria in any fluid. A cluster will develop into one colony and thereby give misleading results. The apparent diminution in the number of bacteria in freshly drawn milk, judged by the number of colonies that develop upon agar plates and known as the germicidal property of milk, is largely a phenomenon of agglutination.

<sup>39</sup> The phenomenon of agglutination had been previously observed by Charrin and Roger in 1899 in the case of the *Bacillus pyocyaneus*. It was also observed by Metchnikoff in the case of the *Vibrio metchnikovi* in 1891. Similar appearance had also been seen by Issaef in 1893.

Agglutination may occur quickly or slowly, depending upon the temperature, the dilution of the serum or fluid containing the agglutinin, and upon other factors; hence, it is important in reporting positive or negative tests in the diagnosis of typhoid fever, Malta fever, and other infections always to state the dilution, the time, the temperature, and other conditions under which the test was made. The interpretation of the results may depend upon these factors.

**Macroscopic Method.**—Agglutination may readily be seen by the naked eye. A uniform suspension of bacteria in a test tube under the action of an agglutinin first becomes granular; the granules increase in size and flock into masses with intervening clear spaces. Then these flocculi settle to the bottom as a precipitate, leaving the supernatant fluid clear.

**Microscopic Method.**—Under the microscope the bacteria are first seen to lose their motion, then to be drawn together into irregular clumps or clusters, which increase in size. The macroscopic method gives higher titers in testing agglutinins than the microscopic method. The latter is subject to several sources of error, and the end point is not as sharply defined as in the macroscopic method.

Agglutination, like almost all chemical processes, takes place more quickly when warm than in the cold. The reaction is accelerated by heat up to 56° C. The clumping usually takes place more slowly with the non-motile bacteria. Capsulated bacteria are peculiarly insusceptible to the ordinary agglutinating powers of immune serum. Certain strains of some species of bacteria agglutinate more readily than others. Thus, the typhoid bacillus is usually agglutinated readily with its specific serum, but some strains are agglutinated with considerable difficulty; in general, when first isolated, they resist agglutination. This resistance or "immunity" of the microorganism usually wears off after a number of subcultures. A very interesting phenomenon in agglutination which has considerable practical importance is the so-called proagglutinoid zone; that is, bacteria sometimes will not agglutinate in a stronger dilution, whereas they agglutinate readily in a weaker. The proagglutinoid zone is occasionally found with the typhoid bacillus, but especially with the *Micrococcus melitensis*. Thus, this coccus may give no reaction in a dilution between 1-10 and 1-100, whereas it will clump strongly at 1-200 and higher.

Agglutinins are not very resistant to light, putrefactive processes, and dryness. They are very active at a temperature of 55° to 56° C., but are destroyed at 65° to 70° C. They are very sensitive to acids; they are partially held back by a Pasteur-Chamberland filter; they are not dialyzable. They may be preserved for a very long time in dried serum protected from light and moisture.

The chemical composition of the agglutinins is not known. Like

antitoxin and other antibodies, they come down with the globulins when precipitated with ammonium sulphate. They unite directly with the bacteria or other cells and, according to Ehrlich, contain both a haptophore and an "agglutinophore" group.

Agglutination is not a vital phenomenon of bacterial activity. The microorganisms play a purely passive rôle. Dead bacteria agglutinate readily. Bordet showed conclusively that agglutination is a physical phenomenon, and that the combination of antigen and antibody is one phase and the agglutination another.

Agglutinins may readily be produced by injecting either live or dead bacterial cells into a suitable animal. The injections may be given either subcutaneously, intravenously, intraperitoneally or the microorganisms may be rubbed upon the closely shaven skin. Agglutinins may even be produced by giving the microorganisms by the mouth. Agglutinins in highest concentration may be obtained by repeated injections, every 10 or 12 days, continued over a long period of time. In experimental work in the laboratory rabbits are suitable. Three or four injections into the ear vein of the rabbit, spaced at intervals of 8 or 10 days with cultures of cholera or typhoid, will develop agglutinins in the blood serum when diluted as high as 1 to 5,000 or 1 to 10,000. Where large amounts are needed the horse is the most suitable animal. Agglutinins are also produced in man by the inoculation of bacterial vaccines.

Agglutinins also appear spontaneously in attacks of certain infectious diseases and continue in the blood for some time after convalescence. In typhoid fever they appear about the end of the first week. They are usually weak at first, clumping the typhoid bacilli in a dilution of 1-30 in one hour at the body temperature, and increase with the progress of the disease, so that the serum may agglutinate in dilutions of 1-1,000 or more. In Malta fever agglutinins appear about the fifth day of the disease and may develop in large amount. Thus, the blood serum from a case of Malta fever may agglutinate the *Micrococcus melitensis* in dilutions as high as 1-500,000. Agglutinins may also develop in cholera, dysentery and many other diseases. The reaction of agglutination is not only practical as an aid to diagnosis of disease, but is of considerable practical use as an aid in recognition of the bacteria themselves. Agglutination is usually regarded as diagnostic of races or strains of bacteria; at most it distinguishes one species from another; while complement fixation distinguishes genera.

The reaction of agglutination is not absolutely specific; thus, a typhoid agglutinin will occasionally clump proteus or other not very closely related microorganisms. Thus, Frost found a *Pseudomonas protea* in the Potomac River water that showed quite constantly the characteristic of being agglutinated by specific typhoid immune serum.

However, when animals were injected with the *Ps. protea* they developed agglutinins for this organism, but not for the *B. typhosus*. Further, there is the phenomenon of *group agglutination* or group reaction; that is, typhoid serum will clump the colon bacillus, the paratyphoid, the paracolon bacillus, and other related organisms. However, this occurs only in slightly diluted serum. The reaction is, therefore, specific in a quantitative sense. Thus, a strong cholera or typhoid serum will agglutinate these organisms in dilutions of 1-1,000 and over, whereas the group reactions occur in dilutions of about 1-50 or less. It is very important to remove the group agglutinins by *absorption* before giving a judgment concerning the specificity of any given reaction.

The difference between specific and group agglutinins may be accurately determined by Castellani's method, known as the absorption of agglutinins. The specific agglutinins may be absorbed from the serum, leaving the group agglutinins, or vice versa. The specific agglutinins can only be absorbed by the specific antigen—therefore, absorption results are of value only when we possess the specific bacterium in question. In this country Dochez has used group and specific agglutinins for the classification of pneumococci and Krumweide for the study of the colon-typhoid group.

In addition to the bacteria, the red blood cells, or cells of any sort, trypanosomes and other protozoa may be agglutinated. The agglutination of the red blood cells of the recipient is an important factor in blood transfusions, etc.

We have no satisfactory explanation of agglutination. Analogous phenomena occur in the study of the physical chemistry of colloidal substances. It seems that in agglutination two separate phenomena are involved: the approach of the particles, one to the other, and their adhesion subsequently. The phenomenon may be imitated by coating match sticks with soap, floating them upon the surface of water, in a basin, and then adding sulphuric acid. The agglutinins affect the surface tension between the bacteria and the fluid in which they are suspended in some way, but just how is not quite clear. The probable explanation of agglutination lies in an alteration in the electric charge of the particles. The agglutinins are probably formed in the lymphoid organs, red marrow, and spleen; at least, Pfeiffer and Marx found them early in these organs after injections of cholera vibrios. Metchnikoff found that the peritoneal exudate may be richer in agglutinins than the blood, and believes in that fluid they come from the leukocytes and endothelial cells.

The part played by the agglutinins in immunity is not clear. Although the bacteria are immobilized, this does not particularly favor phagocytosis. Large clusters of bacteria or agglutinated clumps of closely packed cells may even afford a mechanical protection against the

dissolving action of the lysins. Bull <sup>40</sup> has demonstrated that the power of the blood to cause agglutination determines, in large measure, whether after their direct introduction in an experimental way the bacteria are to be removed promptly from the circulation and septicemia avoided, or whether they are to remain there and produce a blood infection. When the bacteria are clumped they accumulate in the organs, in which they are phagocyted.

## ANAPHYLAXIS

Anaphylaxis <sup>41</sup> (*ana*, against, and *phylax*, guard, or *phylaxis*, protection), also called hypersusceptibility, is a condition of unusual or exaggerated susceptibility of the organism to foreign proteins. In other words, anaphylaxis is an altered power of reaction on the part of the body to foreign proteins. The word anaphylaxis was introduced by Richet to describe a condition contrary to prophylaxis. As we now regard the phenomenon, the word is a misnomer, for we look upon the condition of hypersusceptibility as a distinct benefit and advantage to the organism; in fact, immunity against a large class of infectious diseases probably depends upon an altered power of reaction, that is, upon hypersusceptibility or anaphylaxis.

The condition of anaphylaxis may be congenital or acquired, local or general, and is specific in nature. It may be brought about by the introduction of any strange protein into the body. Hypersusceptibility to proteins that are non-poisonous in themselves may readily be induced in certain animals. The animal may be in a condition of hypersusceptibility and immunity at the same time. The two conditions are closely interwoven. The latter is often dependent upon the former. Von Pirquet suggests the term "allergie" to indicate conditions of acquired immunity associated with anaphylaxis. Allergie, as the word indicates (*allos*, change, and *ergon*, action) is an altered power of the organism to react. When this power of reaction is increased we say the body is hypersusceptible, or in a state of anaphylaxis.

*Hypersensitiveness* may be defined as a specific or particular reaction with characteristic symptoms due to the administration of, or contact with, any substance, which, in the majority of the members of the same species of animal, causes no evident disturbance. According to this definition hypersensitiveness is a broad conception, including both anaphylaxis and allergie. *Anaphylaxis* is an antigen-antibody reaction, artificially induced by immunologic processes. *Allergie*, on the other hand, is used to express a natural hypersensitiveness of the individual

<sup>40</sup> *Journ. Exp. Med.*, 1915, XXII, 484; 1916, XXIV, 25.

<sup>41</sup> The present status of the problems of anaphylaxis and the fundamental theories involved is reviewed by Wells, *Physiological Rev.*, Vol. I, No. 1, Jan., 1921.

not produced by immunologic processes, as the exciting agents or allergens are in many cases not capable of producing antibodies. For example, the natural hypersensitiveness of the human being to pollens, the clinical reaction known as hay fever, is admittedly allergic.

**Examples of Anaphylaxis.**—In the case of vaccinia, the reaction to a primary “take” appears after an incubation of four days. In a secondary vaccination the period of incubation is shortened and the clinical reaction lessened. In other words, the power of the organism to react is changed. This power of accelerated or immediate reaction protects the individual. Therefore, the prophylaxis depending upon the anaphylaxis.

The tuberculin and mallein reactions are well-known instances of anaphylaxis. These substances are not poisonous when introduced into a healthy individual, but the tuberculous individual is anaphylactic to tuberculin, and an individual suffering from glanders is in a state of hypersusceptibility to mallein.

A clinical instance of anaphylaxis is the hypersusceptibility of some individuals to pollen—hay fever. Other examples are food “idiosyncrasies,” serum sickness, urticarial and other skin eruptions.

Experimental anaphylaxis may be brought about in various ways, such as the introduction of an alien protein into the body.

**Experimental Anaphylaxis.**—The essential features of experimental anaphylaxis are:

- (1) The *first injection*, consisting of a bland alien protein non-poisonous in itself, which sensitizes the animal;
- (2) An *interval* of about 10 days;
- (3) The *second injection* of the same protein which produces a reaction known as acute anaphylactic shock or other manifestations.

Horse serum, when injected into normal guinea-pigs, causes no symptoms. As much as 20 c. c. may be injected into the peritoneal cavity of a guinea-pig without causing any apparent inconvenience to the animal. Small amounts of horse serum may even be injected directly into the brain without causing any untoward symptoms.

Very characteristic symptoms, however, are produced by horse serum when injected into a susceptible guinea-pig; i. e., one that has received a prior injection of horse serum. In five or ten minutes after subcutaneous injection the pig becomes restless and then manifests indications of respiratory embarrassment by scratching at the mouth, coughing, and sometimes by spasmodic, rapid, or irregular breathing; the pig becomes agitated and there is a discharge of urine and feces. This stage of exhilaration is soon followed by one of paresis or complete paralysis, with spasmodic and difficult breathing. The pig is unable to stand or, if it attempts to move, falls upon its side; when taken up it is limp: spasmodic, jerky, and convulsive movements now supervene. This chain of

symptoms is very characteristic, although they do not always follow in the order given. Pigs in the stage of complete paralysis may fully recover, but usually convulsions appear, and are almost invariably a forerunner of death. Symptoms appear about ten minutes after the injection has been given; occasionally in pigs not very susceptible they are delayed thirty to forty-five minutes. Pigs developing late symptoms are not very susceptible and do not die. Death usually occurs within an hour and frequently in less than thirty minutes. If the second injection be made directly into the brain or circulation, the symptoms are manifested with explosive violence, the animal frequently dying within two or three minutes.

A fall in temperature occurs which in fatal cases may be as great as 13° C. (Pfeiffer). The blood during anaphylactic shock shows a leukopenia and a diminution in complement. The blood pressure falls. When the chest is opened the lungs show a striking condition resembling emphysema. They do not collapse but remain fully distended, forming a cast of the pleural cavities. The heart continues to beat long after respiration has ceased. Asphyxia, due to inspiratory immobilization of the lungs, is, therefore, probably the immediate cause of death.

Judged by the severity of the symptoms of the acute anaphylactic reaction, the guinea-pig is apparently the most susceptible of animals (being 400 times more sensitive than the rabbit, according to Doerr), but probably all animals may be sensitized to a greater or less degree, although our criteria are still too crude to admit of any accurately graded comparison. White mice were long thought to be non-responsive on account of the absence of anaphylactic shock and death from asphyxia, so striking in the guinea-pig; but Schultz and Jordan have shown that white mice do react toward horse serum with restlessness, marked irritability of the skin, passage of urine and feces, and temperature and blood pressure changes. The symptoms vary with the species and also to some degree with the antigen.

In dogs, according to Richet, the principal symptoms are gastro-intestinal. There is immediate vomiting, followed by tenesmus and bloody discharges from the intestines. Death is infrequent, but there may develop a condition of hemorrhagic inflammation in both the large and the small intestine which is called by Richet "chronic anaphylaxis," and by Schittenhelm and Weichardt, "enteritis anaphylactia." Another important sign is the rapid fall in blood pressure, sometimes 80-100 mm.; on account of the relatively enormous amount of smooth muscle in the hepatic vein of the dog, there is a rise in portal pressure and an increased flow of lymph; coagulation of the blood is delayed. Dyspnea is not marked, but, as in other animals, there is initial restlessness and skin irritability; there may be paralysis and death.

Rabbits are apt to react to a reinjection of horse serum by edema

and even necrosis at the site of injection—the “Arthus phenomenon,” a local anaphylaxis. Arthus also described, in non-fatal cases in rabbits, respiratory disturbance, general prostration, fall in blood pressure, and increased peristalsis. In cases of acute lethal anaphylaxis produced in rabbits highly sensitized by repeated minute injections, Auer describes the slow respiration, the sudden falling of the animal on its side with a short chronic convulsion, stoppage of the respiration, weak heart beat, and death within a few minutes.

The reaction to a second injection of serum has been observed, though not studied so carefully, in numerous other animals, e. g., in cows, horses, goats, sheep, and cats, in hens and pigeons, and in certain cold-blooded animals, with symptoms varying according to the species.

It is evident that no one symptom, or group of symptoms, can be taken as an adequate criterion of anaphylaxis in all cases. Different species give a widely differing picture with the same protein agent, because the same organs are not involved to the same degree. An explanation of these differences from the physiological point of view has been given by Schultz. He has shown that serum anaphylaxis is essentially a matter of hypersensitization of smooth muscle in general. He concludes, as a result of his experiments, that, during anaphylactic shock, all smooth muscle contracts. This is fatal to the guinea-pig, owing to the peculiar though normal anatomical condition of its bronchial tree: the mucosal layer of the secondary bronchi is relatively thick in comparison with the lumen, and the contraction of the smooth muscle throws it into folds which completely occlude the bronchi (Schultz and Jordan). The guinea-pig dies of asphyxia, the cause of which is purely local and not in the central nervous system, as the first investigators believed. The bronchi of mice, dogs, and rabbits, however, are relatively poor in smooth muscle, which accounts for the almost complete absence of death from asphyxia. In the dog the contraction of smooth muscle sets up a vigorous intestinal peristalsis and a forced emptying of the urinary bladder; the characteristic initial rise in blood pressure may be due to constriction of the pulmonary, coronary and systemic arteries, and according to Auer, the subsequent marked fall to direct action on the heart muscle itself, particularly of the right side, causing a venous accumulation of blood, an effect typified most strikingly in the rabbit. This provides also an adequate pharmacological explanation of the action of atropin and the anesthetics in alleviating the symptoms of acute anaphylaxis.

**Specificity.**—The anaphylactic reaction is *specific*. Thus, a guinea-pig sensitized with horse serum does not react to a subsequent injection of egg-white, vegetable protein, or milk. The specificity extends even further than this. In order to give rise to anaphylactic symptoms, the protein material given at the first and second injections must be from

the same species or from some closely related species. Thus a guinea-pig sensitized with cow's milk will not react to a subsequent injection of woman's milk. Guinea-pigs sensitized with the albumen of hen's eggs will not react to a subsequent injection of the albumen of the eggs of pigeons, but do react mildly to duck egg-white. This specificity according to species is, therefore, of the same degree as that of certain immune reactions, notably the precipitins; that is, there is a group reaction in the proteins of allied species, but no reaction between the proteins of widely different species or between proteins of widely different origin. The maximum effect at second injection is obtained by the use of the identical protein used for sensitization. Certain sera which react interchangeably to precipitins, as, for example, human and ape, horse and ass, sheep and goat, rat and mouse, remain indistinguishable also by the anaphylactic reaction. The same specificity holds with respect to bacterial proteins: an animal sensitized with typhoid bacilli will react strongly toward paratyphoid, and somewhat toward colon bacilli, but not at all to unrelated genera.

One of the remarkable facts in relation to the specificity of anaphylaxis is that guinea-pigs may be in a condition of anaphylaxis to three protein substances at the same time; for instance, a guinea-pig may be sensitized with egg-white, milk, and horse serum, and subsequently react separately to a second injection of each one of these substances. The guinea-pig may be sensitized by giving these strange proteins either at the same time or different times, in the same place or in different places, or by injecting them separately or mixed. The guinea-pig differentiates each anaphylactogenic protein in a perfectly distinct and separate manner. The animal is susceptible to the second injection of each one of the three substances in the same sense that it is susceptible to three separate infectious diseases.

That there may be exceptions to the rule of species-specificity is shown in the case of the crystalline lens. A guinea-pig sensitized to the lens-extract of one species of animal will react to the lens-extract of widely different species, or even of its own species, but not to other tissues (Andrejew). Here, too, there is an exact parallel in the precipitin reaction which fails to distinguish the lens of one species from that of another (Uhlenhuth). This is an example of organ-specificity. In the vegetable world Osborne has shown that, whereas preparations of globulins from hemp, flax, and squash do not react with each other, gliadin from rye reacts strongly with gliadin from wheat, a result in accord with the fact that by chemical and physical means no differences have been detected which were sufficient to indicate that these gliadins were different substances.

It is probable that only proteins which have a complete or partial chemical identity of structure will react with each other. Differences

too small to be detected by analytic means at our disposal may yet prevent any tendency toward interaction, and the anaphylactic phenomenon is therefore used to determine the fine relationships of proteins. It is evident from these facts, as Osborne concludes, that structural differences exist between very similar proteins of different origin, and that chemically identical proteins apparently do not occur in animals and plants of different species unless they are biologically very closely related.

**Sensitization by Feeding.**—Guinea-pigs may be sensitized by feeding them meat or serum. The fact that guinea-pigs may be rendered susceptible by feeding of strange protein matter opens an interesting question as to whether sensitive guinea-pigs may also be poisoned by feeding with the same protein given after a proper interval of time. If man can be sensitized in a similar way by the eating of certain protein substances, this may throw light on those interesting and obscure cases in which the eating of fish, sea food, or other articles of diet sometimes causes sudden and often serious symptoms resembling those of anaphylaxis in all essential respects.

**Maternal Transmission.**—It has been found that hypersusceptibility to the toxic action of horse serum is transmitted from the mother guinea-pig to her young. This function is solely maternal; the male takes no part whatever in the transmission of these acquired properties. Whether this maternal transmission is hereditary or congenital cannot be definitely stated.

There are certain analogies between the action of tuberculosis and anaphylaxis. Both produce hypersensitiveness and also a certain degree of immunity. Now that it has been proved that hypersensitiveness or anaphylactic action may be transmitted in guinea-pigs, may it not throw light upon the fact that tuberculosis "runs in families"? While there are several recorded instances demonstrating that immunity to certain infectious diseases may be transmitted from a mother to her young, this is, so far as is known, the only recorded instance in which hypersensitiveness or a tendency to a pathologic state has been experimentally shown to be transmitted from a mother to her young.

**Serum Anaphylaxis in Man, or Serum Sickness.**—Serum anaphylaxis in man is met with most frequently following the use of antitoxic sera, and has been carefully described by v. Pirquet and Schick (1905).<sup>42</sup> After an injection of serum (usually in from eight to twelve days) there is apt to be a febrile reaction, now generally known as "serum sickness," or serum disease. The common symptoms are local redness, itching and pain at the point of injection, swelling of the lymph nodes, fever, and a general urticaria lasting from two to six days. In more severe cases there is malaise, albuminuria, pronounced joint pains and even effusions, swelling of the mucous membranes, hoarseness and cough, nausea and

<sup>42</sup> "Serum Krankheit," Wien, 1905.

vomiting, vertigo, and remarkable skin manifestations varying from hyperemias and erythemas to efflorescences resembling measles or scarlatina, and other vasomotor disturbances. There is a striking resemblance between serum sickness and measles.

Rarely there may be subnormal temperature, a weak and rapid pulse, a catarrhal or hemorrhagic enteritis and extreme weakness approaching collapse. These results are independent of the antitoxic qualities of the serum, for Johannessen obtained the same symptoms by introducing normal horse serum into the bodies of perfectly healthy human beings. Indeed, the very earliest animal experiments were particularly concerned in determining whether the antitoxin played any part in the phenomenon, and it was soon conclusively eliminated as a factor.

Both the incidence and the severity of serum sickness are proportional to the amount injected up to a certain point, but the acute (sometimes fatal) reaction in man is more dependent upon the hypersusceptibility of the individual than upon the amount of serum injected. If the serum is "concentrated" (i. e., serum-globulin), the reactions are correspondingly lessened because smaller quantities of the foreign protein are injected, and the albumins and certain other proteins having been eliminated by the partial purification.

The peculiarity of serum sickness in man is that it may follow the first injection of a foreign serum, though only after a definite incubation period corresponding to the time required to sensitize an experimental animal. There is no proof that other animals do not develop a reaction to the first dose which never rises to the threshold of clinical observation; in fact, Ehrlich, Francione, and others have observed a temporary diminution of complement in the blood of guinea-pigs 10-12 days after the first injection. Just how man becomes sensitized is not always clear. It may be by a previous injection of horse serum, or by eating horse meat, or by the introduction of small amounts of horse protein through wounds of the skin, or through the respiratory tract; finally, hereditary transmission may account for the susceptibility.

Besides the typical serum sickness, there has been reported since the introduction of serum therapy a certain small number of unforeseen and fatal catastrophes attending the injection of horse serum into human beings. The following case published by H. F. Gillette will serve to illustrate them all:

"The patient was a man of 52, a subject of asthma. He asked me to administer diphtheria antitoxin to him, hoping it might cure his asthma. I administered 2,000 units under the left scapula with the usual precautions. He had about completed dressing when he said he had a pricking sensation in the neck and chest; soon he sat down and said he could not breathe, nor did he breathe again. . . . His pulse at the wrist remained regular and full for some time after respira-

tion ceased. He had a mild degree of cyanosis and edema of the face. He died in tonic spasms ten minutes after injection. Autopsy revealed no palpable cause of death."

The same author collected 28 cases of collapse or death after serum injection, of which 15 died. There was a common history of previous asthmatic trouble in all but 5 of the 28, and all, after injection, showed common symptoms of sudden intense dyspnea, a sense of overwhelming anxiety, edema and cyanosis of the face, a sudden massive urticaria, tonic muscular spasms and continued beating of the heart long after the ceasing of respiration. Rosenau and Anderson collected 19 cases and were able to examine the serum used in two of them. It was found to be no more toxic to sensitized guinea-pigs than normal horse serum. These cases of severe anaphylactic shock seem susceptible of no other explanation than that the unfortunate individuals had been in some manner, at a previous time, sensitized to horse protein. They present a picture which is almost the counterpart of typical anaphylactic shock in guinea-pigs, and the most striking thing about them is that practically all give a history of respiratory trouble in the past, especially horse-asthma. Schultz and Jordan suggest that these occasional cases of sudden death in man may perhaps be due to an abnormal development of the mucous membrane and smooth muscle of the bronchi (as in asthmatics), and that the smooth muscle, being hypersusceptible, produces asphyxia by sudden contraction. There is evidence<sup>43</sup> indicating that the protein given off by one animal may be absorbed by individuals of different species by way of the lungs. One thing is clear, that these immediate and sometimes fatal reactions are not dependent upon any peculiar property in the serum, but to an altered power of reaction of the individual to the foreign protein injected. The anaphylactic reactions following the injection of serum in man may be summed up briefly as follows:

*Reactions following first injection:*

- (a) "Serum sickness," incubation 8-12 days (common).
- (b) Acute anaphylactic shock, with collapse or death (rare).

*Reactions following second injection:*

- (a) Interval between injections less than 8 days, no reaction.
- (b) Interval 12-40 days, immediate reaction.
- (c) Interval 15 days-6 mos., either immediate or accelerated reaction, or both.
- (d) Interval over 6 mos., accelerated reaction.

The above table represents the usual course of events, but exceptions may occur, and the time intervals are only approximate. Sometimes

<sup>43</sup> Rosenau, M. J., and Amoss, H. L.: *Jour. of Med. Res.*, Sept., 1911, XXV, 1, pp. 35-84.

the reactions do not appear until the third, fourth, or some subsequent injection.

The following precautions are suggested in serum therapy:

(1) Except in urgent cases, avoid injecting horse serum into individuals known to be asthmatic, especially those in whom symptoms are brought on by being around horses.

(2) If hypersensitiveness is suspected, give at first a very small amount of serum subcutaneously, following it in an hour or so with the rest, injecting it exceedingly slowly and avoiding direct injection into the circulation. Sometimes an intradermal injection is given to determine sensitization; this is followed by small desensitizing doses of the serum at intervals of an hour. There is no necessary correlation between skin hypersensitiveness and general anaphylaxis.

(3) In persons known or suspected of being hypersusceptible to horse serum, bovine antitoxin may be used.

#### **Hypersusceptibility and Immunity Produced by Bacterial Proteins.**

—The problem of hypersusceptibility has an important bearing on the question of immunity, and hence the opinion has been expressed that “resistance to disease may largely be gained through a process of hypersusceptibility. Whether this increased susceptibility is an essential element or only one stage in the process of resistance to disease must now engage our attention.” It is now clear that the phenomenon of hypersusceptibility has an important bearing on the prevention and cure of certain infectious processes.

Hypersusceptibility may easily be induced in guinea-pigs with protein extracts obtained from the bacterial cell. The first injection of most of the extract seems comparatively harmless to the animal. A second injection of the same extract shows, however, that profound physiologic changes have taken place. A definite period must elapse between the first and the second injection. The symptoms presented by the guinea-pigs as a result of the second injection resemble those caused by other proteins. The phenomenon induced by a second injection is followed (in certain cases) by an immunity to the corresponding infection.

These results strengthen the belief that the phenomenon of hypersusceptibility has a practical significance in the prevention and cure of certain infectious processes. It also gives a possible explanation of the period of incubation of some of the communicable diseases. Is it a coincidence that the period of incubation of a number of infectious diseases is about seven to fourteen days, which corresponds significantly with the time required to sensitize animals with a strange protein? The mechanism of prevention and cure of tuberculosis finds its readiest explanation in terms of anaphylaxis.

In certain infectious diseases, such as pneumonia, the crisis which

commonly appears about the tenth day may find a somewhat similar explanation. It is evident that disease processes produced by soluble toxins, such as diphtheria and tetanus, do not belong to the category now under consideration.

**Relation of Anaphylaxis to Protein Metabolism.**—The whole problem of protein metabolism seems to be an adjustment in the sense of a defense. The power to assimilate and use foreign proteins is not achieved without a certain amount of violence to the body. The relation between the fundamental facts of protein metabolism and immunity to certain diseases becomes clearer in the light of observations upon anaphylaxis. A deeper insight into these problems will throw light on the fundamental processes concerned in both protein metabolism and immunity.

**Relation of Anaphylaxis to Endotoxins.**—The fact that the great majority of bacteria do not produce soluble poisons, such as diphtheria and tetanus, has led to the belief that in such cases we are dealing with an "endotoxin." The endotoxin has long been regarded as a poisonous substance so intimately associated with the cell that it is not released until the microbic cell is broken up in the body. The inability to demonstrate many of these endotoxins has cast a doubt on their existence and increased the mystery of their action. It now seems probable that the studies on anaphylaxis may throw light upon this question.

When bacteria grow in the body they are dissolved by lytic agencies and the foreign protein thus released may sensitize the body and afterward "poison" it. The bacterial proteins may not be poisonous in themselves in the sense of an "endotoxin." We have, in fact, shown that protein extracts of bacterial cells at the second injection may produce characteristic symptoms, and this reaction may be followed by an immunity to the corresponding infection.

**The Relation of Anaphylaxis to Tuberculosis.**—The tuberculin reaction is one of the best known clinical instances of anaphylaxis. The reaction may be general, local or focal; even anaphylactic shock may occur. The general reaction is manifested by fever and constitutional symptoms; the local reaction by inflammation of the skin (von Pirquet test); the focal reaction by congestion and increased functional activity about the tuberculous lesion. Balwin and Krause have demonstrated that the general, local or focal reactions occur only as a result of an anatomical tubercle. Following a local infection with the tubercle bacillus the tissues generally become hypersusceptible to tuberculin. It has been shown that a local hypersusceptibility may be produced by the direct application of tuberculin to certain tissues (conjunctiva). The same has been demonstrated for the skin, and is probably true of other tissues. This hypersusceptibility of the tissues immediately surrounding a tuberculous focus helps to encapsulate and limit the process. Should

a tubercle bacillus lodge in or on a tissue in a state of tuberculin anaphylaxis, the result is that all of nature's protecting agencies are quickly concentrated on the point where most needed. We conceive that this active power of reacting quickly is not only an important factor in individual prophylaxis against tuberculosis, but is an important agency by which the spread of the disease after it has obtained a lodgment in the body is prevented.

The normal individual does not react to tuberculin. The tuberculous individual reacts promptly, except in the final stage of the disease. The difference between the normal individual and the individual in the final stage of tuberculosis is that the former has not had his anaphylactic powers developed, while the latter has had them developed and disappear.<sup>44</sup> A tuberculous individual in whom the specific power of hypersusceptibility to the tubercle bacillus is broken down presents little or no resistance against the advance of the infection.

We may adduce a practical lesson from this. When tuberculin is used in large or too oft-repeated doses there is a tendency to break down or to exhaust the useful and beneficial hypersusceptible state of the tissues. In accordance with this line of reasoning, therefore, tuberculin would be of benefit in tuberculosis only when used in such a way as to develop and not diminish the power of anaphylaxis of the tissues. This explanation has been borne out in the use of tuberculin, especially as a therapeutic agent in bone, gland and skin tuberculosis, when the process is sluggish. Hence, for therapeutic purposes, it should be used chiefly to stimulate a chronic sluggish process—even then only in small amounts at infrequent intervals, and only when autogenous tuberculin is not secreted.

**Relation of Anaphylaxis to Vaccination.**—When the virus of cowpox is introduced into the skin we implant a colony of microorganisms. They grow day by day, and on the eighth day there is an enormous number of them. The contents of the vesicle will start new colonies on thousands of other arms, but now the antibodies appear and the colony is attacked and digested, and toxic bodies are formed. This is diffused in the neighborhood and we get an intense local inflammation called the areola. Some of the toxic bodies enter the circulation and cause fever, but the microorganisms are killed and we can no longer vaccinate with the contents of the now yellow pustule; two or three days more, the struggle is over, but the antibodies remain a long time. Let us now revaccinate, and a different series of events takes place, for in the meantime the body has become educated and instead of waiting some days before attacking the colony of microorganisms in the skin, starts the attack at once. In other words, there is an immediate reaction—a

<sup>44</sup> The term *antianaphylaxis* is now used to describe the condition when a sensitized animal fails to respond.

changed power of reaction or anaphylaxis. In brief, the first vaccination has sensitized the tissues, so that they respond at once upon the second vaccination.

The invading microorganisms, attacked at once, are soon destroyed—they are given no chance to multiply, and little toxin is formed. This attractive explanation of the immunity to smallpox or cowpox, developed by von Pirquet, shows that the prophylaxis depends upon the anaphylaxis. See *Immediate and Accelerated Reactions*, page 18.

**Relation of Anaphylaxis to Food "Idiosyncrasies."**—Many persons are susceptible to some particular article of diet. The symptoms produced are vasomotor disturbances, skin eruptions, gastro-intestinal disorders, and respiratory difficulty. The articles of diet usually responsible are shell-fish, fish, strawberries, tomatoes, pork, cereals, eggs, milk,—the list is very long, including even honey. Fish, tomatoes, and cheese are apt to produce urticarias; cereal, pork and milk, erythemas and eczemas; eggs, asthmatic symptoms. There is, however, no constancy in this regard. Collapse may result in a few minutes from the ingestion of a very small amount of the particular substance to which a person is hyper-susceptible.

These cases of food "idiosyncrasies" are instances of local and general anaphylaxis. Bronfenbrenner<sup>45</sup> demonstrated the presence of specific antibodies in the blood of a young girl, 17 years old, who was subject to asthmatic attacks and severe gastro-intestinal disturbances, following the ingestion of small quantities of egg protein. In most cases the susceptibility is clearly inherited, in some it may be acquired. When there is difficulty in determining which food is responsible, the skin test may be employed. This consists in rubbing a drop of the food itself, or a watery extract, into a scratch upon the skin. The reaction comes on within thirty minutes, as a pink-red papule, and declines rapidly. The relation between the local and general reactions is not always clear.

Antianaphylaxis to this condition may be brought about by "immunizing" the subject with increasing doses of the responsible antigen given by the mouth. Peptone, 0.4 to 0.5 gram, by the mouth before eating also acts as a desensitizing agent. The peptone seems to be polyvalent for most of the proteins causing the anaphylaxis.

**Eczema.**—Towle and Talbot were among the first definitely to reveal that a goodly proportion of eczematous infants were passing stools containing an excess of fats and starch. A correction of diet will relieve most of these infants in a few weeks. In cases where eczematous infants and older children do not reveal an excess of starch or fat, they are usually anaphylactic to egg albumin, milk, oatmeal, or some other food containing protein. In chronic eczema, the great majority of these victims exhibit anaphylactic reactions to one or more types of food sub-

<sup>45</sup> *Journ. Exp. Med.*, 1915, XXI, No. 3.

stances. Only about 20 per cent. of eczematous individuals do not appear sensitized to any of the common food types.

**Relation of Anaphylaxis to Hay Fever.**—Hay fever may be caused by the pollen of grasses and certain plants, such as ragweed, goldenrod, etc.; by emanations from animals, especially horses and cats; by suggestion, as in nervous coryza; and by changes in chemical reaction, as when hyperacidity of the gastric juice causes the mucous membranes to swell and discharge a watery secretion. Hay fever is a characteristic symptom-complex that depends entirely upon an inherited predisposition on the part of the respiratory and conjunctival mucous membranes, and not upon the influence of a specific agent.

Persons who are susceptible to pollen represent instances of local anaphylaxis of the respiratory mucosa. The symptoms are mainly local, but also general. The particular pollen responsible in any individual case may be determined by placing a drop of a watery extract upon a scratch on the skin. A positive reaction manifests itself in five or ten minutes as an elevation with a hyperemic border and itching. Certain foods, especially eggs, give rise to respiratory difficulty, asthmatic in nature.

**Rose colds** are associated with pollen from roses, timothy, daisies, etc. Usually they occur early and are mild. Rose colds may be helped by inoculations with their respective proteins. The problem is different with hay fever due to ragweed, for the pollen of ragweed is a microscopic bur with penetrating properties. In cases due to ragweed, it is necessary to consider massive dosage, also secondary infections which follow injury to the mucosa.

**Relation of Anaphylaxis to Drugs; Anaphylactoid Reactions.**—Most of the persons who show idiosyncrasies to certain drugs give a clear history of inherited hypersensitiveness. The symptoms of drug reaction are the same as those that occur with foods, i. e., coryza, cough, bronchial spasm with urticaria in some cases, or angioneuritic edema, and frequently gastro-intestinal manifestations, with pain, vomiting and diarrhea. These symptoms are quite separate and apart from any normal or toxic action of the drug. The class of drugs known as antipyretics occasionally produce chills and pyrexia, sometimes cardiac collapse. In practically all these cases, there is a marked eosinophilia, from 10 to 15 per cent. Symptoms usually appear within a few hours after the administration of the drug, but are sometimes delayed for days.

The drugs that may act as exciting agents are many: metals, the halogens, alkaloids, methane derivatives, coal tar products, benzol derivatives, also resins, turpentine, sandalwood oil, cubebs, copaiba balsam, and others.

**Other Practical Relations of Anaphylaxis.**—Other conditions which have been explained in whole or part on the theory of anaphylaxis are

puerperal eclampsia, sympathetic ophthalmia, the onset of labor, the crisis in pneumonia, the spasmophilic diathesis, the symptoms attendant on the rupture of the cysts in echinococcus disease, etc. The anaphylactic reaction is also used in diagnosis, and in forensic medicine in the identification of blood stains, and, finally, may be used as a scientific instrument for the detection of minute amounts of protein.

#### REFERENCES TO IMMUNITY

Emery's book upon "Immunity and Specific Therapy" and Zinsser's book on "Immunity" are recommended to the reader who desires a more extended review upon the subject. Kolle and Wassermann's "Handbuch der Pathogenen Mikroorganismen" has also been consulted, as well as Kraus and Levaditi's "Handbuch der Technik und Methodik der Immunitätsforschung." These volumes also contain selected bibliographies.

The laboratory methods of Immunology are described in Kolmer's "Practical text book of Infection, Immunity and Specific Therapy."

The current literature upon immunity will be found in the *Journal of Immunology* and *Zeitschrift für Immunitätsforschungen*.

For those who desire to dip deeper into the subject the original reference to many of the fundamental studies will be found in "Collected Studies on Immunity" by Ehrlich, translated by Bolduan; "Studies on Immunity" by Bordet, translated by Gay; "Studies in Immunization" by Wright; "L'Immunité dans les Maladies Infestieuses" by Metchnikoff, translated by Binnie; and Ricketts, H. T.: "Infection, Immunity and Serum Therapy in Relation to the Infectious Diseases Which Attack Man," Chicago, 1906.

## CHAPTER II

### HEREDITY AND EUGENICS

Heredity may be defined as the genetic relation between successive generations. It is a condition of all organic evolution. Castle defines heredity as organic resemblance based on descent.

It is now perfectly evident that heredity is one of the fundamental factors in preventive medicine—and of first importance in sociology. It is well known to students of biology that education and environment have but a limited power to improve imperfect human protoplasm.

One of the best protections we have against diseases of body and mind is that which is inherited from our forebears. The whole problem of improving the human stock, not only from the medical view, but from the broader sociologic standpoint, is based upon the breeding of the fit and elimination of the unfit. The science of eugenics (normal genesis), therefore, assumes especial importance in preventive medicine. The physician, as well as the sanitarian, stands impotent before many deplorable conditions both in the individual and in society at large, which are inherited from our ancestors and are, therefore, incurable—but largely preventable. We are interested in educating the present generation to the facts of eugenics so that future generations may have that best of all birthrights—good human protoplasm.

The discoveries of Mendel have made it quite clear how certain characters are inherited, why certain characters skip a generation and reappear in the grandchildren, and why it is that certain defects are carried from generation to generation through many centuries.<sup>1</sup> The defects transmitted hereditarily are not all of equal practical importance. Thus, it makes comparatively little difference to the individual if he has a supernumerary spleen, an extra finger, or an unusual arrangement of the lobes of the liver. The defects which are of especial importance both to the individual and to succeeding generations are the defects of the nervous system. These comprise the class known as defectives. A slight defect in the structure of the brain which would be unnoticed in the lung, bone, or musculature may render the individual vicious instead of useful. The principal factors which are believed to

<sup>1</sup> Mendel's work has not only made it possible for us to predict with precision whether certain good or bad traits will or will not appear in the future offspring, but also to foretell with considerable precision in what proportion certain characters will appear and reappear.

start a line of defectives are inbreeding, syphilis, and alcohol; also nervous or physical diseases, mental or nervous exhaustion, and excesses and poisons of all kinds.<sup>2</sup>

### DEFECTIVES

Mental defectives are due to restricted mental development and must be regarded as children, and whatever their age must be treated as children. They are unmoral, not immoral. They need treatment, not punishment, for they are as innocent as children, not naturally bad, vicious or wicked.

**Recognition.**—The supposition that mentally defective persons may readily be recognized by their physical appearance, or by some outward expression, such as the movement of the eyes, is a mistake. It is also important not to confuse illiteracy with mental deficiency.

The defective individual is very easily recognized when the condition is well marked. The mental abnormality is usually accompanied by prominent physical defects known as the stigmata of degeneration (Lombroso and Weismann). The typical degenerate is of poor bodily development; the brain is smaller than normal, with convolutions less abundant, and less fully formed. He has a degraded physiognomy, lacks capacity for sustained attention or for prolonged thought, is cunning rather than intelligent, deficient in moral sense—in all points resembling the stigmata of the lower, less developed races of our species. The whole gives the impression of a reversion to a lower type. An unfortunate side to this problem is that degenerates and defectives generally are not only irresponsible morally, but are very prolific. They lack self-control and have abnormal sexual appetites. Defectives beget defectives, and thus insanity, nervous diseases, moral and physical degeneracy are propagated.

**Mongolianism.**—The Mongolian<sup>3</sup> type is described by Shuttleworth as follows: "The skull is a short oval, the transverse and longitudinal diameters approximating, while there is a tendency to parallelism of the frontal and occipital planes. Children of this type have a skin coarse in epidermis, if not furfuraceous; many have sore eyelids, some fissured lips; but one of the most striking peculiarities is the state of the tongue, which is transversely fissured, and has hypertrophied papillae. Dr. John Thomson states that in the early weeks of life the tongue is normal: between the third and ninth months the papillae get enlarged, while during the third and fourth years the transverse fissures appear. This latter

<sup>2</sup> The real cause or method of origin of some defective characters that are transmitted hereditarily is no better understood than the origin of "sports" or mutations.

<sup>3</sup> This type has no connection with the Mongolian race. It is so named on account of the resemblance to that type of countenance.

peculiarity is possibly due to tongue sucking, which is so common in this type of defective, acting on an abnormally vulnerable mucous membrane. Many of them have almond-shaped eyes, obliquely set, and this feature, with the squat nose, epicanthic fold, and wiry hair, gives the Mongol aspect from which they derive their name. The hands are usually broad and the fingers short, and often the little finger is incurved. The feet also are characteristically clumsy, with a marked cleft between the big toe and the next one. Laxity of the joints is a marked feature. There is no reason to believe that they are essentially *unfinished* children, and that their peculiar appearance is really that of a phase of fetal life."

Mongolianism is definite and easily recognized and should be diagnosed early, usually before the sixth or eighth month. This is important for the sake of the parents. Goddard states that a diagnosis of Mongolianism settles the following points: (1) The condition is not hereditary. (2) It is more frequent in the better families. (3) The child will never develop beyond the seven-year mentality, and the great majority have a mentality of almost exactly four years. Consequently (4) they must always be cared for. Unpleasant as the duty is, yet in the long run it is a kindness to the parents to inform them of such a diagnosis.

**Feeble-minded—Idiots, Imbeciles and Morons.**—Feeble-minded persons are now commonly divided into three groups: (1) *idiots*, which comprise those whose mentality does not advance beyond normal children of two years; (2) *imbeciles*, those whose minds remain at about the fourth-year period; and (3) *morons* or fools, those whose mental condition does not get farther than about the twelve-year age. Mild grades are called *psychopathic inferiority*. All grades of mental inferiority between the moron and the normal occur. In addition, there is a group above the moron whose conduct shows that they are not normal. These are sometimes called *dull normal*, or *backward*. Of these three groups the moron is perhaps the most important from every standpoint, for this is the group of defectives that propagates itself, and the crop is large. The high grade defective or moron is the most troublesome, partly because he is not easily recognized as defective, and partly because he has sufficient mentality to go about by himself and get into all kinds of mischief, either on his own account or led on by someone else. The male morons grow up into paupers, drinkers, hoboos and ne'er-do-wells and fill our hospitals and asylums. The female morons grow up into irresponsible women who replenish the ranks of the prostitutes and other defectives.

The Royal Commission of England reports that in that country the feeble-minded are increasing at twice the rate of the general population. Butler of Indiana states that feeble-mindedness produces more pauperism, degeneracy, and crime than any other source; that it touches every form of charitable activity; that it is felt in every part of the state, and

affects, in some way, all the people, and that its cost is beyond comprehension. The Committee of Visitors of the State Charities of New York reported that there are in that state 32,000 feeble-minded persons (1914). Of these, 4,900 are provided for in institutions especially designed for their care, and 4,500 in other institutions, leaving at large 22,600. It has been estimated that of the 32,000 feeble-minded, 10,000 are girls and women of child-bearing age, 1,750 of whom are cared for in institutions designed for the care of such persons, and 1,625 are confined in reformatories, prisons, and almshouses, leaving about 7,000 at large in the community. Goddard estimates that in the way of spreading disease, immorality, and increasing the stock of the feeble-minded, a girl or a woman of this class, of child-bearing age, is three times as great a menace to the community as is a feeble-minded boy or man. It is estimated that the feeble-minded constitute 25 to 50 per cent. of the inmates of our prisons, 15 to 30 per cent. of the almshouses, and a still larger percentage of prostitutes.

Upwards of 2 per cent. of juveniles are so defective mentally as to be incapable of self-support and self-direction, and are largely irresponsible.

Mental deficiency can be acquired in persons with good heredity. This sometimes occurs as a result of injury to the brain, or of cerebral hemorrhages occurring in the course of acute febrile infections of childhood. Other causes are:—Bacterial toxins which may permanently injure the brain cells and prevent their development; cerebrospinal fever; local meningitis, resulting from middle ear disease; or serious impairment of the special senses, etc.

*Intelligence Quotient.*—Albert Binet first suggested that it was possible to take the mental measure of normal and defective mentality. He devised a measure scale for intelligence. He deduced from his experience the following formula: "Children who are under nine years of age and show a backwardness of more than two years, are probably mental defectives to the extent of being actually feeble-minded; those who are nine years or more and show a backwardness of more than three years are also feeble-minded." Goddard states that Binet's formula is well within the truth. More accurate methods of measurement, however, have been devised, and specialists use the "Intelligence Quotient" (I. Q.). This is obtained by dividing the *mental* age by the age in years, which gives in the case of backward children a fraction. If this fraction is less than 0.75 there is a very high degree of certainty that the person is feeble-minded. If the fraction is greater than 0.80, the person while backward or dull normal is not feeble-minded. If the I. Q. is between 0.75 and 0.80, the case may be a doubtful one and is frequently called "border-line."

The general mental characteristics that can be determined without

special psychological tests are (1) lack of control of emotions and impulses, (2) inability to adapt to new conditions, (3) inability to generalize from experiences or to deal with abstractions, (4) general lack of good judgment and good sense.

**Prevention of Propagation of Defectives.**—Four methods have been proposed to prevent the propagation of defectives: (1) education; (2) legislation; (3) segregation; (4) surgery.

*Education.*—Education directed toward the defective is a failure, for he is incapable of profiting by the lessons. The education of the better class of the community is indirectly helpful in calling attention to the situation as being largely preventable, and to the necessity and means for controlling it.

*Restrictive Legislation.*—Restrictive legislation is a praiseworthy effort, but has signally failed as a preventive measure, for the evident reason that it only adds illegitimacy to degeneracy, and thus the children enter on life's battle doubly handicapped. Minnesota has a law providing that within the bounds of the state no marriage shall be permitted, either party to which is epileptic, imbecile, feeble-minded, or afflicted with insanity, unless the woman be over forty-five. Michigan, Delaware, Connecticut, Indiana, New Jersey, and North Dakota have also passed laws for the purpose of preventing marriage among defectives.

*Segregation.*—Segregation would be an ideal and humane method of isolating those who are incapable of having normal offspring, but the segregation of all degenerates and defectives would be an enormous and impractical task. Further, the great difficulty is to detect the unfit individual who starts a strain of defectives and degenerates. It is evidently a hopeless task to know where to draw the line between the fit and the unfit, so that for the present we must be satisfied to enforce restrictive measures upon only those who are evident and well-marked examples. Insane asylums, homes for epileptics, reformatory schools, as well as special hospitals and institutions for advanced cases must not be regarded as preventive measures in the true sense, for such segregation provides care and comfort as a terminal measure; that is, it is usually a last resort. Frequently defectives propagate their kind before and sometimes after they are interned in such institutions. Preference, nevertheless, should be given to women of child-bearing age in institutional care.

Although segregation of all persons with higher types of mental defect is never likely to be accomplished, there is hope of devising a plan of registration and guardianship in the community which will protect a great many and prevent their marriage.<sup>4</sup>

<sup>4</sup>Fernard, "What is Practicable in the Way of Prevention of Mental Defect," a pamphlet distributed by the National Committee for Mental Hygiene, 1915. Also, Salmon, "Outlines of a State Policy for Dealing with Mental Deficiency," *Medical Record*, April 17, 1915.

*Surgery.*—Sterilization has been proposed as a means of controlling the propagation of defectives. This is done either by severing the *vas deferens* or the Fallopian tube. At the Indiana Reformatory Dr. Sharp carries out the law <sup>5</sup> of that state providing for the sterilization of defectives. The operation of *vasectomy* consists of ligation and resection of a small portion of the *vas deferens*. The operation is very simple and easy to perform. It may be done without an anesthetic, either local or general. As performed by Dr. Sharp it requires about three minutes, and the subject returns to his work immediately, suffering no inconvenience and in no way hampered in his pursuit of life, liberty, and happiness, but is effectively sterilized. In 456 cases Dr. Sharp has had no unfavorable symptoms. The operation is performed as follows: After cleansing the scrotum with soap and water, followed by alcohol, the spermatic cord is grasped between the thumb and index finger of the left hand. The *vas deferens* is detected, firmly held and fixed with a pair of bullet forceps. It is then exposed by a small incision and drawn through the scrotum wound by means of a tenaculum. It is stripped of all membranes and the accompanying artery, ligated above and severed, care being taken to cut away any portion of the *vas deferens* that may have been damaged in the manipulation. This is done in order to promote absorption from the interstitial cells of Leydig, and to avoid cystic degeneration of the testicle. The retraction of the muscle closes the skin wound and no stitch, collodion, or adhesive plaster is needed. There is no diminution of the sexual power or pleasure. The discharge at the orgasm is but slightly decreased.

The operation in the female is more difficult, but if carefully done is no more hazardous. The Fallopian tubes are reached through a

<sup>5</sup>The Indiana law reads as follows:

Whereas, Heredity plays a most important part in the transmission of crime, idiocy, and imbecility;

Therefore, Be it enacted by the General Assembly of the State of Indiana, That on and after the passage of this act it shall be compulsory for each and every institution in the State, entrusted with the care of confirmed criminals, idiots, rapists, and imbeciles, to appoint upon its staff, in addition to the regular institutional physician, two (2) skilled surgeons of recognized ability, whose duty it shall be, in conjunction with the chief physician of the institution, to examine the mental and physical condition of such inmates as are recommended by the institutional physician and board of managers. If, in the judgment of this committee of experts and the board of managers, procreation is inadvisable and there is no probability of improvement of the mental and physical condition of the inmate, it shall be lawful for the surgeons to perform such operation for the prevention of procreation as shall be decided safest and most effective. But this operation shall not be performed except in cases that have been pronounced unimprovable. . . .

Eleven other states provide for the sterilization of either criminals or the feeble-minded, viz.: California, Connecticut, Iowa, Kansas, Michigan, Nevada, North Dakota, New York, New Jersey, Washington, and Wisconsin. The constitutionality of the law has been appealed to the Supreme Court in Iowa. *Bull. of the Univ. of Wisconsin*, No. 82, 1 May, 1914.

median incision and ligated near the uterus and severed beyond the ligature.

Opinions vary greatly concerning the proper use of sterilizing criminals, insane, degenerates, and defectives generally. There is no doubt concerning its effectiveness.

Sterilization is a measure which contains great potential possibilities for abuse and injustice. It probably will never receive general acceptance on account of the difficulty of determining upon whom the operation shall be done. Even in perfectly clear cases, such as the insane, the epileptic, or the high grade degenerate, the harm has often been done before the operation is decided upon.

**Statistics of Defectives.**—The large number of defectives and unfit in our country may be gleaned from the following figures showing the number of inmates in state institutions in 1913.<sup>6</sup>

In institutions for—	
Feeble-minded .....	28,805*
Insane .....	205,198**
Criminalistic (including delinquent and wayward) ..	84,328
Epileptic .....	7,313*
Inebriate .....	463
Tuberculous .....	5,995
Blind and deaf .....	11,991
Deformed .....	456
Dependent .....	24,089
Total .....	368,638

\* As of January 1, 1916.

\*\* As of June 30, 1914.

The last census report for the United States gives data relative to the dependents and defectives in institutions; the number not in institutions can only be guessed at. Kellicott gives the following approximate numbers in our country in 1904:

Insane and feeble-minded, at least .....	200,000
Blind .....	100,000
Deaf and dumb .....	100,000
Paupers in institutions .....	80,000
Prisoners .....	100,000
Juvenile delinquents in institutions .....	23,000

The number of persons cared for in hospitals, dispensaries, and "homes" of various kinds in the year 1904 was in excess of two million. All these are not defectives, but many suffer from preventable disabilities.

Salmon estimates that there are about four mentally defectives per 1,000 of population.

<sup>6</sup> These figures were compiled by the Bureau of the Census, *The Eugenics Record Office*, and the National Committee for Mental Hygiene.

Goddard states that there are between 300,000 and 400,000 feeble-minded in the United States. Further, that two-thirds of them owe their condition to heredity, and that they are propagating their kind at a rate two to six times as fast as the good stock. It is estimated that the feeble-minded constitute 25 to 40 per cent. of the inmates of our prisons, 15 to 30 per cent. of the inmates of almshouses, and a still larger percentage of prostitutes.

We have to support about 500,000 insane, feeble-minded, epileptic, blind, and deaf, 80,000 prisoners, and 100,000 paupers, at a cost of \$100,000,000 per year. A new plague affecting 2 per cent. of the population and costing this vast treasure would instantly attract universal attention. One-sixth of the total appropriation of the State of Massachusetts is for the maintenance of insane and feeble-minded in institutions. We have become so used to crime, disease, and degeneracy that we take them as necessary evils. "That many of them were so in the world's-ignorance is granted; that they must remain so is denied."

Statistical studies seem to indicate a rapid (at least an unnecessary) increase of the unfit, defective, insane, criminal, and, on the other hand, a slow increase, or even a decrease (?), of the fit, normal, or gifted stocks. It is plain to the student of eugenics how such conditions account for the rise and fall of nations.

The United States census of 1880 reported 40,942 insane in hospitals and 51,017 not in hospitals; a total of 91,959 known insane. In 1903 it was estimated that there was a total of 180,000 in the United States. Thus, the ratio of known insane in the total population was 225 per 100,000 in 1903, as compared with 183 per 100,000 in 1880. On January 1st, 1920, there were 232,680 patients with mental disease in hospitals for the insane in this country. Including those on parole, the number would be over 250,000 (see page 422). These figures must not be taken as an index of the increase of insanity in the population at large—for institutional care has been growing much more popular during the past decade, especially since more humane methods have been adopted. Further, the classification of insanity now includes many cases that were formerly little noticed.<sup>7</sup> This subject is fully discussed in Section II.

<sup>7</sup>A special census of the insane confined in institutions was taken by the Bureau of the Census in 1910, and it was found that 187,454 patients were confined in hospitals for the insane in the continental United States.

While the population of the United States increased about 11 per cent. in the interval between 1904 and 1910, the population in insane asylums increased about 25 per cent. The number of insane in asylums per 100,000 population increased from 186.2 in 1904 to 203.8 in 1910. The number of persons annually committed to hospitals for the insane per 100,000 population increased from 61.5 in 1904 to 65.9 in 1910. If these ratios are accepted as representing insanity rates, it would appear that the number of persons becoming insane, in a community comprising 100,000 persons, was greater by 4.4 in 1910 than it was in 1904. It must be remembered, however, that these figures include only the insane

The comparatively large and increasing numbers of defectives and weaklings among the civilized races compared with wild animals may be accounted for by the fact that atavism and reversion are more frequently met with in artificially cultivated strains, such as civilized man; and the further fact that our charitable and philanthropic efforts foster and even favor the unfit.

**Degenerate Families.**—A careful study has been made of the records of several families in which the mating of unfit individuals has begotten a swarm of unfit descendants.

One of the best known families of this type is the so-called Jukes family of New York State investigated by Dugdale. This family is traced from the five daughters of a lazy and irresponsible fisherman born in 1720. In five generations the descendants of Jukes numbered about 1,200 persons, including nearly 200 who married into it. The histories of 540 of these are well-known, and about 500 more are partly known. Some 300 died in infancy. Of the remaining 900, 310 were professional paupers living in almshouses (a total of 2,300 years); 440 were physically wrecked by their own diseased wickedness; more than half of the women were prostitutes; 130 were convicted criminals; 60 were habitual thieves; 7 were murderers. Not one had even a common school education; only 20 learned a trade, and 10 of these learned it in State's prison. The descendants of Jukes in five generations have cost New York State over one million and a quarter dollars, and the cost is still going on.

Probably the most complete family history of this kind ever worked out is that of the "Familie Zero," a Swiss family whose pedigree has been studied by Jörger. In the seventeenth century this family divided into three lines. Two of these have ever since remained valued and highly respected families, while the third has descended to the depths. This third line was established by a man who was himself the result of two generations of intermarriage, the second tainted with insanity. He was of a roving disposition, and in the Valla Fontana found an Italian vagrant wife of vicious character. Their son inherited fully the parental traits and himself married a member of a German vagabond family—Marcus. This marriage sealed the fate of their hundreds of descendants. The pair had seven children, all characterized by vagabondage, thievery, who are committed to hospitals. As to the number of cases of insanity not resulting in commitments to hospitals the census has no data. It is entirely possible that the increase in the number of commitments per 100,000 population is not due to any considerable degree to an increased prevalence of insanity, but simply to the extension of this method of caring for the insane. It is a change which might result from an increase in the number of institutions of this class and from the increasing disposition on the part of the public to resort to such institutions. In this connection it may be noted that the number of institutions for the insane reported by the census increased from 328 in 1904 to 372 in 1910, an increase of about 13 per cent. The average number of inmates per institution increased from 458 in 1904 to 504 in 1910.

drunkenness, mental and physical defects, and immorality (Kellicott). How much of this is due to heredity and how much to environment will be discussed presently.

Another interesting example of the same type has been described by Poellmann. This family was established by two daughters of a woman drunkard who in five or six generations produced, all told, 834 descendants. The histories of 709 of these are known. Of the 709, 107 were of illegitimate birth, 64 were inmates of almshouses, 162 were professional beggars, 164 were prostitutes, and 17 procurers, 76 had served sentences in prison, aggregating 116 years, 7 were condemned for murder.

Dr. Henry H. Goddard<sup>8</sup> has investigated and compiled the results of his work on the heredity of a most remarkable family, the Kallikak family. During the Revolutionary days, the first Martin Kallikak (the name is fictitious), descended from a long line of good English ancestry, took advantage of a feeble-minded girl. The result of their indulgence was a feeble-minded son. This son married a normal woman. They in turn produced five feeble-minded and two normal children. Practically all of the descendants of these defectives have been traced, as well as those of the two normals. The tragic story follows:

From both normal and defective descendants of this union came a long line of defective stock. There were 480 in all. Of these 36 were illegitimate, 33 sexually immoral, 24 confirmed alcoholics, and 3 epilep-

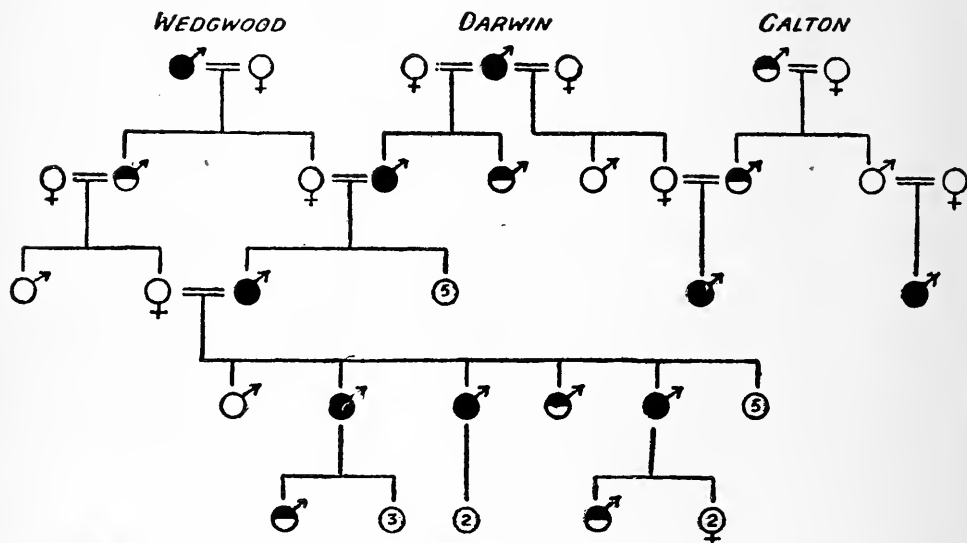

FIG. 62.—HISTORY OF THE FAMILY ZERO (condensed from Jörger's data, partly after Davenport).

ties. Eighty-two died in infancy, 3 were criminal, 8 kept houses of ill fame, and 143 were distinctly feeble-minded. Only 46 were found who were apparently normal. The rest are unknown or doubtful. But the scion of the good family who started this long line of delinquent and defective progeny is also responsible for a strain of an entirely different character. After the Revolutionary War was over, he married a Quaker girl of good ancestry and settled down to live a respectable life after the traditions of his forefathers. From this legal union with a normal woman there have been 496 descendants. All of these except two have been of normal mentality. The exceptions were cases of insanity, presumably inherited through marriage with an outside strain in which there was a constitutional psychopathic tendency. In all the 496 there is not an instance of feeble-mindedness. The offspring descended from this side of the house have universally occupied positions in the upper walks of life. They have never been criminals or ne'er-do-wells. On the other hand, there has not been a single instance of exceptional ability among the descendants of the first Martin Kallikak and the feeble-minded girl. Most of these descendants have failed to rise above the dead level of mediocrity; indeed, most of them have fallen far below even this minimum standard.

The fact that the descendants of both the normal and the feeble-minded mother have been traced and studied in every conceivable environment, and that the respective strains have always been true to type, tends to confirm the belief that heredity has been the determining factor in the formation of their respective characters. In the cities the descendants of the legal marriage with the normal woman are physicians, lawyers, and prominent business men, while the descendants of the feeble-minded mother are almost invariably found in the slums. In the rural districts the descendants of the normal mother and her consort are wealthy and influential farmers, while the others never rise above the rank of farm laborers and shiftless men and women, who are unable to subsist without the aid of charity. Many representatives of the defective branch are inmates of almshouses, while there are no paupers at all among the normal descendants.

In many ways this study of Goddard's far outweighs in importance the famous comparison by Dr. Winship of the Jukes and Edwards families. In that case the simple fact was demonstrated that a good family like that of the illustrious Jonathan Edwards had given rise to innumerable examples of the highest intellectual and moral worth, whereas the criminal Jukes for seven generations contributed nothing to the common good and cost the state of New York large sums of money. But the Jukes family and the Edwards family had no ancestor in common. Their environment was totally different and they lived in

entirely separate communities. Although from sociologic and economic points of view the history of the Jukes family and its comparison with that of the family of Jonathan Edwards has great value, it is of but scant scientific importance as compared with that of the Kallikak family, for here a natural object-lesson in eugenics shows unmistakably the manner in which after-coming generations from a given mating receive the characteristics of the dominant strain, which in the elder (illegitimate) Kallikak line was the inferior strain, with only a debased and enfeebled heritage to hand on.<sup>9</sup>

◐ shows a man of scientific ability ; ● shows a man of scientific ability, who is also a Fellow of the Royal Society ; 5 shows five other children, and so on.

FIG. 63.—HISTORY (CONDENSED AND INCOMPLETE) OF THREE MARKEDLY ABLE FAMILIES (After Whentham) (Kellicott).

In contrast to these we have the descendants of the families of Wedgwood, Darwin, and Galton, the Edwards family and the Ward family. These three noted families contained a large number of statesmen, jurists, professors, physicians, officers in the army and navy, prominent authors and writers, and occasionally men and women of genius. They show a long line of usefulness in every department of social progress, and not one of them ever has been convicted of a crime.

How much of this is due to heredity and how much to environment are debatable questions. Students of biology are convinced that heredity plays the major rôle in the lives of the individuals in the above-mentioned families. In how far such extreme instances as those given above

<sup>9</sup> *J. A. M. A.*, Oct. 26, 1912, LIX, 17, p. 1545.

represent the rule or exceptions it will require much additional data and long years of study to determine (see pages 425 and 638).

## EUGENICS

The science of eugenics has been defined as "the science of being well born." According to Galton, "eugenics is the study of the agencies under social control that may improve or impair the racial qualities of future generations either physically or mentally."

The aim of eugenics is to increase the number of best specimens in each class; that done, leave them to work out their common civilization in their own way. It also aims to leave a good heritage to the next generation and to repress the propagation of the vicious and defective classes.

The success of eugenics depends almost entirely upon our knowledge of heredity and sociology. Therefore, the fundamental principles of heredity should be familiar to all students of preventive medicine.

The present movement started in 1865 when Francis Galton showed that mental qualities are inherited, just as are physical qualities, and pointed out that this opened a way to an improvement of the race in all respects. Galton's work on "Hereditary Genius," published in 1869, again emphasized the possibility and desirability of improving the natural qualities of the human race. The word "eugenics" was coined in 1883 in his "Inquiries Into the Human Faculty."

There is no doubt concerning the desirability of breeding better human stock, but how this may be accomplished practically is a difficult question. The program of the eugenicist is perplexing and complicated: To follow the theoretical extremists would require a social revolution—a change from the present method of haphazard mating. The threshold of the subject has scarcely been passed, and we must bear in mind that some of the striking men of genius from whom the world has greatly profited have been individuals whom the student of genetics would regard as degenerates or defectives. Eugenics does not mean free love, nor does the eugenicist recommend Burbanking the human race to produce great physical strength, beauty, endurance, mental or moral power. One point only in the program is perfectly clear, and that is that a check should be placed upon the propagation of the crop of defectives by means already pointed out.

The known facts of heredity and the study of eugenics make us examine more critically some of the directions which preventive medicine, including philanthropy and social uplift, has taken. We must now ask ourselves the question whether it would not be better for the future generations if we helped the fit instead of concentrating all our attention

and sympathies upon the weakling and the unfit. These are problems raised by Galton, who questions whether some of our philanthropic efforts are well balanced and well directed.

It is important to recognize that many diseases are due to defects of society. Sociology, therefore, must come to the aid of preventive medicine. Crime is often a defect that needs treatment rather than punishment. Poverty is one of the chief causes of diseases, and ignorance one of its first allies. Hence, constructive reforms must aim for social justice, education, and the teachings of eugenics.

According to the teachings of genetics, all men are not created free and equal; but bound by their protoplasmic make-up and unequal in their powers and responsibilities.

It is evidently now of great importance to collect a large number of pedigrees, in which the data shall be stated with scientific exactness and in minute detail. Such a mass of facts may then be studied in the light of science in order to determine in how far the laws of heredity apply to human characters. This is being done by the Eugenics Record Office at Cold Springs Harbor, New York, under the patronage of the Carnegie Institution.

Specifically, the Record Office seeks pedigrees of families in which one or more of the following traits appear: short stature, tallness, corpulency; special talents in music, art, literature, mechanics, invention, and mathematics; rheumatism, multiple sclerosis, hereditary ataxy, Ménière's disease, chorea of all forms, eye defects of all forms, otosclerosis, peculiarities of hair, skin, and nails (especially red hair), albinism, harelip and cleft palate, peculiarities of the teeth, cancer, Thomsen's disease, hemophilia, exophthalmic goiter, diabetes, alkaptonuria, gout, peculiarities of the hands and feet and of other parts of the skeleton.

In brief, then, the aim of eugenics is through heredity to give the individual the greatest of all birthrights, good human protoplasm—and to eliminate, as far as may be possible, bad human protoplasm.

## PRINCIPLES OF HEREDITY

For a clearer understanding of the hereditary transmission of disease, malformations, and defects, it is necessary to have an understanding of the principal views upon organic evolution and the theories of heredity. The student of preventive medicine should especially have a clear comprehension of Mendel's work, which has thrown a flood of light upon the problems before us. Mendel has opened new vistas in biology, which have a practical bearing upon public health work. It is evidently impossible in a short space to do justice to such large subjects as evolution and heredity, and the student is, therefore, referred

to the authorities given at the end of this chapter, which will repay careful study.

**Variation.**—It has been a matter of common observation that like *tends* to beget like rather than “like *begets* like,” for there is a tendency toward new departures.

Two distinct sorts of divergences may appear among the members of a single family. The first is known as variation; the second as mutation.

By variation we understand those slight differences which invariably distinguish all the members of every family. They consist of individual differences which affect every part and every character. Such differences are also known as fluctuating, normal, or continuous variations to distinguish them from abnormal, definite, or discontinuous variations, which are more properly termed mutations. As examples of variation in man we may cite the differences in size or stature, color of skin and eyes, curliness of hair, configuration of features, etc.

Darwin lays particular emphasis upon the importance of variation in his views of organic evolution.

**Darwin's Theory—The Survival of the Fittest.**—Darwin's views<sup>10</sup> of heredity form the basis of his theory of organic evolution. Two separate factors are primarily concerned: (1) the fact of fluctuating variation, that is, that no two members of the same family ever resemble one another exactly; and (2) the occurrence of a struggle for existence between organisms, owing to the geometric rate of increase of living things. From these two facts it follows that, when a change of environment takes place, certain members of an existing species will be somewhat better adapted than others to withstand the new conditions, and the former will tend to survive to the exclusion of the latter. Darwin assumes that during long series of generations this process will result in a steady change in the character of the species in the direction of better adaptation to the new conditions. In other words, Darwin considers that an accumulation of a series of small changes due to the influence of environment are transmitted hereditarily through natural selection.

The remarkable effects produced in the case of domestic animals and plants by the action of artificial selection greatly influenced Darwin's views upon the selective influences which exist in nature. Darwin believed in the hereditary transmission of acquired characters and regarded organic evolution as proceeding by a slow, gradual, or continuous process. There can be no doubt that natural and sexual selection have a great influence, but whether sufficient to originate new species or even new specific characters is a question. Now that the transmission of acquired characters is denied by students of heredity, and the

<sup>10</sup> Darwin: “The Origin of Species,” etc.

fact that DeVries has actually observed new species arise suddenly, this portion of Darwin's theory of organic evolution and the origin of species is receiving critical examination.

Darwin firmly believed that the characters of organisms can be modified by selection, and he made this the foundation stone of his theory of evolution. The brilliancy of the mutation theory of DeVries, coupled with his great service to biology in rediscovering the Mendelian laws, has somewhat dazzled our eyes. Castle believes, after ten years of continuous work in selection, that much may be accomplished by this means quite apart from the process of mutation, and considers that the work of DeVries himself argues strongly in favor of this idea, although his interpretation of it is adverse to selection. From the evidence at hand we must conclude that Darwin was right in assigning great importance to selection in evolution, that progress results not merely from sorting out particular combinations by large and striking unit characters, but also from the selection of slight differences in the potentiality of gametes representing the same unit character combinations.

**Mutation.**—Mutations comprise definite differences, usually of considerable magnitude—differences that indicate specific characters or the beginning of new species. Such differences are also known as abnormal, definite, or discontinuous variations, but more properly they are termed mutations, sometimes "sports." Mutations may be either useful or harmful. They arise "spontaneously" and are transmitted in accordance with Mendel's law. As examples of mutations in man we may cite albinism, polydactylism, brachydactylism, etc.

DeVries, Bateson, and the "mutationists" are convinced that mutation is a much more important factor in the origin of species than variation, as understood by Darwin. In the light of Mendel's work mutations appear to be unit characters which arise "spontaneously"—in some instances they represent recessive characters that have remained dormant for many generations.

**DeVries—Discontinuous Evolution.**—The observations of DeVries upon the evening primrose (*Oenothera lamarckiana*) convinced him that species may arise suddenly, that evolution is discontinuous and goes by leaps and bounds rather than by the slow or continuous process of organic evolution described by Darwin.

Mutation is the term applied by DeVries to express the process of origination of a new species or a new specific character, when this takes place by the discontinuous method at a single step. DeVries believes that this is the most important, if not the sole, method by which new species or specific characters arise. To those who are convinced that acquired characters are not inherited the explanations of Lamarck and Darwin have always been incomplete. Darwin insisted that nature does

not make jumps and that new species arise slowly through the action of natural selection on minute variations—a gradual or continuous evolution.<sup>11</sup> From his experiments DeVries concludes that when selection is really efficient the full possible effects of this process are exhausted in quite a small number of generations, and that then the only further effect of selection is to keep up the standard already arrived at. DeVries actually observed quite a number of new types of plants which arose suddenly and naturally. When they made their appearance the majority of the new types came true to seed. With regard to the causes of mutation little is known, unless we assume that they represent unit characters which have long remained recessive.

**Weismann's Views.**—Weismann's<sup>12</sup> views are based largely upon his assumption that the germ plasm is distinct from the body and that acquired characters are not inherited. The parent is composed biologically of somatic, or body cells, which are mortal, and reproduction cells, or germ plasm, which are distinct, continuous, immortal. The germ cells undergo the least modification from their original condition. Indeed, Weismann believes that there is no reason for supposing that they have undergone any modification at all. From this point of view we may consider the nature of a given series of animals as being determined only by the particular series of cells which constitute the direct ancestry of the germ cells in each individual. The cells which make up the bodily structure may be regarded as the result of so many offshoots which come to an end at the death of the organism and have no progeny of their own.

The minute study of the germ cells taken in connection with modern experimental work on the methods by which inheritance takes place shows a strong tendency to confirm Weismann's views, so far as the inheritance of distinct and definite characters is concerned.

Wilson<sup>13</sup> has expressed Weismann's theory as follows: It is a reversal of the true point of view to regard inheritance as taking place from the body of the parent to that of the child. The child inherits from the

FIG. 64.—WILSON'S THEORY OF INHERITANCE MODIFIED BY LOCK (G, germ cells; S, somatic cells).

<sup>11</sup> Darwin, however, recognized the facts of mutations or "sports" as he called them and dwelt upon their importance.

<sup>12</sup> Weismann, A.: "Essays upon Heredity," 1889, and "The Evolution Theory," 1906.

<sup>13</sup> Wilson: "The Cell in Development and Inheritance," p. 13.

parent germ cell, not from the parent body, and the germ cell owes its characters not to the body which bears it, but to its descent from a pre-existing germ cell of the same kind. Thus, the body is, as it were, an offshoot from the germ cell. As far as inheritance is concerned, the body is merely the carrier of the germ cells which are held in trust for coming generations. Fig. 64 illustrates Wilson's theory of inheritance as modified by Lock.

**Mendel's Law.**—We are indebted to Mendel<sup>14</sup> for one of the most important observations of biology—the most important, in fact, with reference to heredity. The essential factors of Mendel's discovery are: (1) unit characters, (2) dominance, (3) segregation. By a unit character is understood any characteristic of an individual that is transmitted from parent to offspring through successive generations and which conforms to the following: When parents with complementary unit characters unite, it is found that one character predominates over the other. This is known as *dominance*. It has further been found that the unit characters contributed by the respective parents do not, as a rule, blend, but remain separate or distinct. This is known as *segregation*. The principles of segregation and dominance have been found to apply to the inheritance of many characters in animals and plants. It should be carefully borne in mind that the unit characters themselves are not transmitted as such in the germ cells. Just what is transmitted is not definitely known. It is quite sure that the only thing that is inherited in the germ cells is something which determines the development of the unit character. This something is called a *determiner*.

The essence of this great discovery was published by Mendel in a short paper in 1866. By some extraordinary chance Mendel's observations were entirely lost sight of until the same facts were independently rediscovered in 1899 by DeVries, working in Holland, by Correns in Germany, and by Tschermak in Austria.

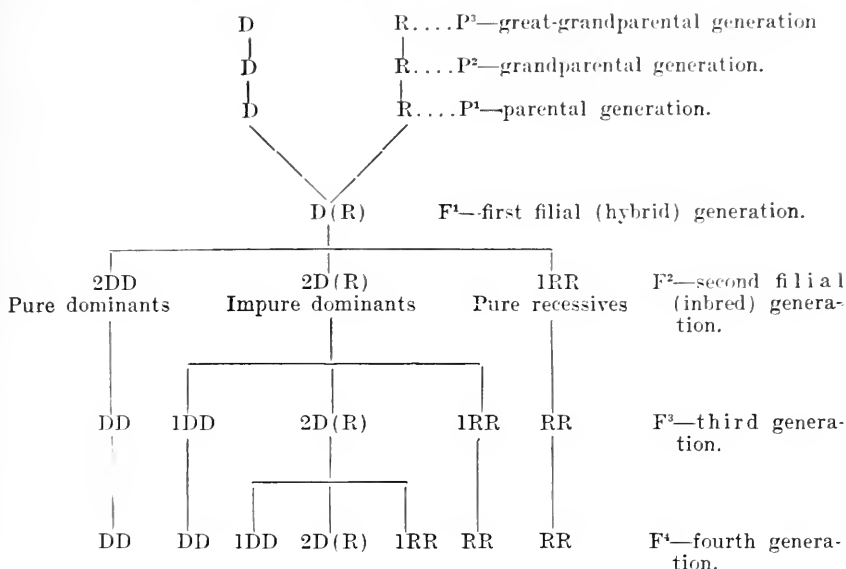

Mendel's law may best be understood from a concrete illustration. One of the simplest cases is that of the heredity of color in the Andalusian fowl, which has been so clearly described by Bateson.

There are two established color varieties of this fowl: one with a great deal of black and one that is white with some black markings or splashes.

<sup>14</sup>Gregor Johann Mendel was born July 22, 1822, at Heizendorf in Austrian Silesia. In 1843 he entered the Augustine Convent at Altbrunn as a novice, and was ordained priest in 1847. Mendel was a teacher of natural science in the Brunn Realschule from 1853 to 1868, when he was appointed abbot of his monastery.

Mendel published only the results of his work upon hybridization with peas and a few of his experiments with *Hieracium*. The original paper on "Hybridization" was published in the *Verh. Naturf. Ver.* in Brunn, Abhandlungen IV, 1865, which appeared in 1866; the paper on "*Hieracium*" appeared in the same journal, VIII, 1869. The student is advised to read "Mendel's Principles of Heredity" by W. Bateson, 1909, in which he will find a translation of these two important papers. A clear exposition is also given by R. C. Punnett in his book entitled "Mendelism" (1911).

A SCHEMATIC REPRESENTATION OF MENDEL'S LAW

D and R represent complementary unit characters, D the dominant character, and R the recessive character. D(R) represents a dominant with the recessive character unexpressed but potentially present. DD means pure dominants, and RR pure recessives.

For convenience we may refer to these as the black and white varieties respectively. Each of these breeds true by itself. Black mated with black produce none but black offspring. White mated with white produce none but white offspring. Crossing black and white, however, results in the production of fowls with a sort of grayish color called "blue" by the fancier, though in reality it is a fine mixture of black and white. If we continue to breed succeeding generations from these blue hybrid fowls we get three different colored forms. Some will be blue, like the parents, some black, like one grandparent, some white, like the other grandparent. Further, these different colors appear in certain definite proportions among the three classes of descendants. Of the total number of the immediate offspring of the hybrid blues, approximately one-half will be blue, like the parents, approximately one-fourth black, and one-fourth white, like each of the grandparents. Thus, black bred together produce only blacks; the white similarly produce only whites; the blues, on the other hand, when bred together produce a progeny sorting into three classes, and in the same proportion as that produced by the blues of the original hybrid generation. The fact that the black grandchildren and the white grandchildren respectively breed true is a very important fact. In this illustration no race of the hybrid

blue character can be established, for the blues always produce blacks and whites as well as blues (see Fig. 65).

Another instance which illustrates the phenomenon of dominant and recessive characters as well as segregation is here given. If black and

FIG. 65.—DIAGRAM SHOWING THE COURSE OF COLOR HEREDITY IN THE ANDALUSIAN FOWL, IN WHICH ONE COLOR DOES NOT COMPLETELY DOMINATE ANOTHER. *P*, parental generation. The offspring of this cross constitute *F*<sub>1</sub>, the first filial or hybrid generation. *F*<sub>2</sub>, the second filial generation. Bottom row, third filial generation. (Kellicott.)

white varieties of guinea-pigs are crossed the offspring are all black, like one parent; that is, when black and white characters are brought together in the guinea-pig, these do not appear to blend into gray or "blue," as in the case of the Andalusian fowl, but one character alone appears.

FIG. 66.—DIAGRAM SHOWING THE COURSE OF COLOR HEREDITY IN THE GUINEA-PIG, IN WHICH ONE COLOR (BLACK) COMPLETELY DOMINATES ANOTHER (WHITE). Reference letters as in Fig. 65. (Kellicott.)

The black seems to cover up or wipe out the white. The black color is, therefore, said to be dominant and the white recessive. The white character, however, has not disappeared, for when the black offspring are crossed together the progeny falls into two groups: some black and some

white. Three-fourths of the progeny are black; that is, they resemble the hybrid form and at the same time one of the grandparents, while the remaining fourth resemble the other white grandparent. Some of these blacks will breed true and are, therefore, known as *homozygotes*. Some of the blacks contain a mixture of the black and white characters and are, therefore, known as *heterozygotes*. The hereditary transmission of the color character in these two illustrations through the germ cell is shown in the accompanying diagram.

*Unit characters* may either be *positive* or *negative*; that is, they may be due to the presence or absence of "something" in the germ cell or sperm cell. This something, known as a determiner, is a force, a molecular structure or an enzyme (?) in the nuclear matter of the germ plasm. Thus, the determiner in the case of pigment is not the pigment itself, but something that activates pigment production. These determiners are transmitted in the germ plasm and are the only things that are truly transmitted. The determiner may be either in the ovum or the sperm.

An heritable character may be due to the presence or absence of a determiner in the germ plasm of both parents. When a character is due to the presence of a determiner it is called positive, when due to the absence of a determiner, negative. Thus, a brown eye depends on a determiner that produces the brown-colored pigment, while the blue eye depends upon the absence of such a determiner. It is not always easy to anticipate whether a given character is positive or negative. For instance, long hair in Angora cats, sheep, or guinea-pigs is apparently not due to a factor added to short hair, but rather to an absence of a determiner that stops growth in short-haired animals.

One of the most important conclusions from Mendel's observations is that the different inherited traits act independently; that is, they do not blend. In other words, the definitely heritable characters act as independent units that are without any apparent relation to other peculiarities of the individual concern. Furthermore, these units do not interfere with each other. It follows that all the unit characters of an individual are to be regarded as mutually independent assemblages. This is the doctrine of unit characters. According to this doctrine, each individual is of dual origin, paternal and maternal, and each individual is made up of a mosaic of inherited characters, some of which may be dominant, others recessive. The idea of unit characters capable of being inherited independently of one another is one of the most important conceptions which has been added to our knowledge of heredity. We now know from the phenomenon of segregation what constitutes purity in a strain of animals or plants; that is, purity does not depend upon the length of time during which a race has exhibited a constant character, for a strain of absolute purity may arise from the second generation of

a cross. Mendel's law has not only explained many facts in heredity, but also has important practical bearing in the improvement of the breeds of cultivated plants and domestic animals.

**Atavism and Reversion.**—Atavism (from *atavus*, a grandfather) is the inheritance of properties not manifest in either parent, but present in the grandfather or some relatively remote ancestor. Mendel's observations upon recessive characters now make plain some of the phenomena known as atavism. According to Castle, atavism or reversion to an ancestral condition can be completely explained by the Mendelian principles. It is nothing more or less than the reassertion of recessive unit characters that have long been overshadowed by dominant characters. It seems that recessive characters may not be lost, no matter how long they remain latent or dormant.

The term "atavism" is sometimes employed to mean any reversionary condition, whether favorable or unfavorable, while the term "reversion" means a return in the offspring to a lower type, usually of some remote ancestor. The degenerations which run in families may be instances either of atavism or reversion, or mutation.

Darwin's classical experiment illustrating reversion consisted in crossing a barbed fan-tail female pigeon with a barbed spot male and producing offspring hardly distinguishable from the wild Shetland species of blue-rock pigeon (*Colomba livia*). This is a case of reversion, in which an artificially bred and highly specialized race quickly recovered characters which had been lost during many generations. A foal is sometimes born with a few stripes on its forelegs, as if reminding us of striped wild horses. Highly cultivated and specialized flowers and vegetables have a tendency to revert, and sometimes produce forms hardly distinguishable from their wild progenitors.

Reversion is due to the reassertion of latent ancestral characters. It is an impelling hereditary force which must be taken into account. True reversion may arise in pure bred races, but is much more frequent as the result of hybridization.

The facts of reversion and atavism are of peculiar interest to man, for the reason that the human species has, through unconscious selection and conscious effort, improved the race to its present point of superiority. Whether civilized man to-day is superior to ancient races may be doubted, but the fact is plain that civilization is breeding an artificial and highly specialized strain that shows artificial departures from primitive stock.

It is well known that the high bred and "fancy" races of the domesticated animals show a marked tendency to reversion or deterioration of type. Likewise, the human race shows the same tendency to revert to types resembling its forebears. The present level attained by the more highly civilized races can only be maintained by a continua-

tion of that struggle for improvement, progress, and desire for perfection which is an inborn characteristic and an essential element of progress. Owing to the artificial position to which the human race has brought itself, it becomes necessary to continue the struggle—to stand still means rapid deterioration. Some of the stigmata of degeneration and hereditary defects may be accounted for by this natural tendency on the part of an artificially nurtured standard to slip backward.

**Galton's Law of Filial Regression.**—Filial regression has nothing to do with reversion. The law of filial regression concretely stated is that offspring are not likely to differ from mediocrity in a given direction so widely as their parents do in the same direction. There is a continual tendency to sustain a specific average or a stock average.

Let us take a simple instance from Professor Karl Pearson's "Grammar of Science." Suppose a group of fathers with a stature of 72 in.; the mean height of their sons is 70.8 in.—a regression toward the mean height of the general population. On the other hand, fathers with a mean height of 66 in. give a group of sons a mean height 68.3 in.—again nearer the mean height of the general population. The "regression" works both ways—there is a leveling up as well as a leveling down. "The father with a great excess of the character contributes sons with an excess, but a less excess of it; the father with a great defect of the character contributes sons with a defect, but less of it" (Thompson).

## THE CELL IN HEREDITY

Each parent (male and female) is composed biologically of somatic or body cells, which are mortal, and germ plasm which is distinct, continuous, immortal. The development and embryology of the germ and sperm cells are of particular interest to the student of heredity.

The view has gained ground and general acceptance that the nucleus is the chief or exclusive bearer of the hereditary characters; that is, the female nuclear material transmits the characters of the mother and her forebears and the male nucleus those of the father and his forebears to the offspring.

Cells divide and multiply in two ways: (1) by direct division or amitosis, and (2) by indirect division or mitosis. Direct division occurs more frequently than is usually suspected. The process appears to be a very simple one; the nucleus divides without any preliminary arrangement of its structure, the cytoplasm is constricted, and presently we have two cells in place of one. Indirect division or mitosis appears to be the natural mode of cell development. The chromatin, which is the deeply staining matter in the nucleus, rearranges itself from its

"resting" stage. After a complicated process the nuclear matter forms itself into a long cylindrical thread known as the linene thread. This then divides into links or chromosomes.<sup>15</sup> The chromosomes are of special interest, for they are believed to carry the "determiners."

In mitotic division each chromosome is divided in half longitudinally, as a stick might be split up the middle, and after a very complex process the halves of each split chromosome migrate to opposite poles. Then each centrosome attracts a group of chromosomes consisting of just one-half of the original chromatin material. Each group then, in orderly fashion, rounds itself into a new nucleus, and the body of the cell (the cytoplasm) constricts across the equatorial plane, and two cells are formed.

Every species of plant or animal has a fixed and characteristic number of chromosomes which regularly recurs in the division of all of its cells and in all forms arising by sexual reproduction the number is even. Thus, in some of the sharks the number of chromosomes is 36, in certain gastropodes it is 32; in the mouse and salamander, the trout, the lily, 24; in the worm *Sagitta*, 18; in the ox and guinea-pig, 16; in man the number was formerly stated as 16, now 24. In crustaceans the number of chromosomes may be as high as 168. In a few insects the females have in their body cells one chromosome in addition to the number possessed by the males. This has been interpreted as bearing upon the determination of sex.

Van Beneden in 1885 discovered the important fact that the nucleus of the ovum and the nucleus of the spermatozoön which unite in fertilization contain each one-half of the number of chromosomes characteristic of the body cells.

As both the germ and sperm cells contain only half the number of chromosomes, a reduction must take place in the history of these cells; in fact, alike in the history of the germ cell and in the history of the sperm cell, there is a parallel reduction in the number of chromosomes to one-half. This reduction appears to be a preparation of the reproduction cells for their subsequent union, and a means by which the number of chromosomes is held constant in the species.

In sexual reproduction each centrosome attracts a group of chromosomes, half of which are of paternal origin and half of maternal origin. This is interpreted as meaning that the paternal and maternal chromosomes that unite to form the new zygote probably carry the hereditary characters.

The gist and meaning of the whole process to the student of heredity is the precisely equal partition of the maternal and paternal con-

<sup>15</sup> For a full understanding of cell division the student is referred to one of the standard text-books upon Cytology, or Minot's "Embryology"; also, to E. B. Wilson's "The Cell in Development and Inheritance," 2d Ed., 1900.

tributions, so that each of the zygote cells that is to form a new individual has a nucleus half from the mother and half from the father.

Although the ovum is much larger than the spermatozoön, each contributes equally so far as the amount of nuclear matter is concerned; the new individual is dual in its origin, and the offspring is a double creature and retains its duality to its dying day, and transmits it to succeeding generations.

Professor E. B. Wilson states the generally accepted opinion somewhat as follows: As the ovum is much larger it is believed to furnish the initial capital—including, it may be, a legacy of food yolk—for the early development of the embryo. From both parents alike comes the inherited organization which has its seat (according to most biologists) in the readily stainable chromatin rods of the nuclei. From the father comes a little body, the centrosome, which organizes the machinery of division by which the egg splits up and distributes the dual inheritance equally between the daughter cells.

The ovum may be stimulated to segmentation without the sperm cell (parthenogenesis). When this happens individuals are produced similar to, but not as vigorous as, the normal types. The sperm cell similarly is able to develop without the nuclear matter of the egg. In other words, the ovum and the sperm each contain potential factors for the new individual. As we have already seen, in accordance with Weismann's theory, that the germ plasma is independent of the body and is continuous; therefore, acquired characters not affecting the germ plasma are not inherited in accordance with this conception.

Foreign bodies carried along by either the germ or sperm cells are examples of congenital transmission and not instances of true heredity; therefore, in the present-day conception of heredity it is not possible for a microbial disease to be transmitted hereditarily, even though the microorganism is contained in either the germ or the sperm. Thus, hens may be caused to lay colored eggs by feeding the hens with aniline dyes. Anaphylaxis is an example of a transmitted property, but the "substance," whatever it is, seems to be carried along with the maternal germ cell as a foreign body. In the case of syphilis, the *Treponema pallidum* may be carried along by the germ or sperm, and the disease is said to be transmitted hereditarily, but, strictly, the microorganism is carried as a foreign body and not as a unit character or constituent part of the nuclear matter.

## STATISTICAL METHODS

### [*Vital Statistics, Section IX*]

Statistical methods applied to biology have been termed biometry by Professor Karl Pearson. Francis Galton's book on "Natural In-

heritance" is a pioneer in the subject, and embodies a lucid introduction to the statistical study of variation and inheritance. The health officer must be familiar with statistical methods not only in their application to biology, but as they relate to vital statistics. The health officer who lacks the quantitative view or who fails to grasp the statistical values of the facts and factors in preventive medicine works under a decided handicap. The sanitarian who is ignorant of statistical methods must necessarily grope in the dark. Efficiency and economy in public

FIG. 67.—MODEL TO ILLUSTRATE THE LAW OF PROBABILITY OR "CHANCE." *A*, Peas held in container at top of board. *B*, Peas after having fallen through the obstructions into the vertical compartments below. The curve connecting the tops of the columns of peas is the normal probability curve.

health work depend not alone upon a knowledge of the biological sciences, but also upon a correct sense of proportion. The statistical method is a strong lever which makes for sane administration, economy in expenditure, efficiency of effort; in short, successful results.

Statistics deal with groups rather than with individuals. It must be understood that the *average* of a group may represent something quite different from any individual which the group contains. Also a group may contain individuals of very diverse natures. In collecting statistical material the data must be gathered without any preconceived ideas and without neglecting any members. In this respect statistical methods differ from biological methods, which require careful discrimination of data.

The quantitative determination of a character may be made by various methods, as by counting or by measurement.

The statistical method may be illustrated by a simple model, such as that suggested by Galton. This is a modification of the familiar bagatelle board covered with glass and arranged as shown in Fig. 67. A funnel-shaped container at the top of the board is filled with peas or similar objects. Below this is a regular series of obstacles symmetrically arranged, and at the bottom of the board is a row of vertical compartments also arranged symmetrically with reference to the chief axis of the whole system. If we allow the peas to run through the funnel and fall among the obstacles into the compartments below, we find that their distribution will follow certain laws capable of precise mathe-

FIG. 68.—NORMAL CURVE. (Lock.)

matical description. The distribution of the peas may be predicted with fair accuracy. The middle compartment will receive the most; the compartments next the middle somewhat fewer; those further from the middle still fewer; and the end compartment fewest. If we connect the top of each column of peas by a curved line we get a curve known as the "normal frequency curve." A curve of the same essential character would result from plotting the dimensions of a thousand cobblestones, the deviation from the bull's eye in a target-shooting contest, or by plotting the variability of a biologic character, such as the stature or strength of men, the spread of sparrows' wings, the number of rays on scallop shells, or of ray flowers of daisies.

While from the above law of probability we know quite definitely what the general distribution of the peas will be, we do not know at all the future position of any single pea. Of this we can speak only in terms of probability. The chances are very high that it will fall in one of the three middle compartments, very low that it will be in one of

the extreme compartments. The chances are equal that any individual pea will fall above or below the average or middle position. We therefore see that in any group there are many more individuals near the average than there are in the classes removed from the average, and the farther the removal of a class from the average the smaller the number of individuals in that class; hence, we have the important fact in statistical methods that an individual may belong to a group without representing it fairly. In order to get a correct idea of the whole group we must know first to what extent deviation in each direction occurs above and below the group average; and, second, the average amount by which each individual of the group deviates from this group average; that is, we must know the amount of variability as well as the extent of the greatest divergence from the average. Hence, we have the following definitions and corollaries:

**Definitions.**—A *variate*, or *variable*, is one of the separate numerical values from which a curve of variability can be constructed. It may be defined as a single magnitude-determination of character. *Character* may be defined as any quality common to a number of individuals. The accuracy of the statistical method is usually proportionate to the number of variates out of which the curve is built. The biometrician usually deals with some such number as 100 or more variates. The total number of variates is represented by the area inclosed by the curve, and it will be seen that half the total number of variates falls between the two quartiles and half outside them.

Variates may be lines, terms, units, events, items, etc. If of the same magnitude, they are said to be uniform. If the series is made up of different magnitudes, these differ from each other (and from uniformity) by *deviations*.

A *class* may be defined as a group of variates, all of which show a particular value or a value falling between certain limits. The term is also used to express quantities that cannot be measured or expressed by figures; as sex, nationality, etc.

The *frequency of a class* is the number of variates which it contains.

*Groups* are measurable and can be expressed by figures; as age, height, weight, etc.

The *mean* is the average of all the values from which the curve is constructed. In any actual case obtained by practical methods, the position of the mode, the median, and the mean will only be approximately the same because such a curve is never perfectly symmetrical.

The *amount of variation* shown by a particular group of variates is measured by the degree of slope of the curve. A steep curve indicates greater variability and a flat curve denotes less variability. In other words, the deviations are greater when the curve is steeper, and vice versa.

The rejection of *extreme variates* in treating statistical series is allowable only under exceptional circumstances. In many physical measurements, for instance, Chauvenet's or some other mathematical criterion should be used to test the suspicion that single extreme variates should be rejected. Even then, while the observations might be excluded in calculating, they should, however, be published.

In any series of variates, the *quartile* is the middle term of each half of a series. In the curve representing the series, quartiles are lines dividing each half of the curve area into two equal parts. They are shown at Q and Q' (Fig. 68).<sup>16</sup> A large series of variates can have, similarly, decentiles, percentiles, etc., which are useful to show the distribution of groups.

The *median* is a perpendicular line which divides the area of the curve into two equal halves. It is also the middle variate. This implies, of course, that the variates must be arranged in the order of their ascending or descending magnitude, which is not necessary in the mean or average determination. If the series is made up of an even number of variates, the median lies half-way between the two middle ones (A, Fig. 69). It is, then, the magnitude above which, and below which, 50 per cent. of the variates occur. The median is like the mean only when the series of variates, or the curve representing that series, is symmetrical. If the curve has a decided tendency to skewness or asymmetry, the median may have little value. It may be determined by simple graphic methods outlined above, without the use of mathematics.

The *mode* may be defined as the class with the greatest frequency. It is necessary to distinguish between the empirical and the theoretical mode.

The *empirical mode* is found by inspection of the seriated data and is found to be the most frequent variate, the most probable length, the number appearing the greatest number of times, etc. It is then possible for the mode to be at the end of a series; moreover, the modal value is unaffected by any values at the extreme ends of the series.

By *theoretical mode* we mean the mode of the theoretical curve most closely agreeing with the observed data. In a normal curve, it is the longest perpendicular which can be drawn from the base line to meet the curve itself (M, Fig. 68). The normal curve is symmetrical on either side of the mode; that is to say, two perpendiculars drawn from the base to the curve on either side of the mode and at the same distance from it will be equal in length.

The mean, median, and mode of a symmetrical or normal curve therefore coincide. In an asymmetrical curve, the mode may have greater significance than the mean or average. In this case, the mode lies on the opposite side of the median from the mean; and the abscissal distance from the median to the mode is double the distance from the

<sup>16</sup> And at B and C, Fig. 69.

median to the mean; or mode = mean - 3 (mean - median). That is, it is significant when the abscissal distance from the median to the mode is double the distance from the median to the mean.

The *standard deviation* of a normal curve is the measure of variability and is expressed shortly as  $\sigma$ . The value of  $\sigma$  is found by multiplying the square of the deviation of each class from the mean (or mode) by the frequency of the class, adding together the series of products so obtained, dividing this number of the total number of

FIG. 69.—CURVE MADE UP OF VARIATES. Example on page 637. *A* = position of the median; *B*, that of the lower quartile, and *C*, of the upper quartile. *D* represents the mode, while *E* shows the position of the mean.

variates, extracting the square root of the result, and multiplying by the number of units in the class arranged.

In the curve, the standard deviation may be roughly determined by adding the distance of the two quartiles from the median. It serves to indicate whether or not the departures from the mean are small or great. The closer the variates group themselves around the mean, the smaller the standard deviation.

The *coefficient of variability* is a purely abstract number obtained by dividing the standard deviation by the magnitude of the mean in any particular case and multiplying the result by 100. It is the ratio of the standard deviation to the mean. It is an excellent measure of variability, and is used to compare this quality among different characters, or in the same character among different groups, particularly if the means differ widely.

In a normal distribution, the *probable error* of a single variate in the series of observations, is defined as that departure from either side of the mean within which one-half of the variates are found. The probable error is dealt with mostly in correlation. When the difference between two means is greater than three times the probable error, the difference is significant. The probable error of the standard deviation, of the mean, median, etc., are all occasionally useful.

In the following example, the figures represent a hypothetical series.

## EXAMPLE

GROUP OF VARIATES	DIFFERENCE BE- TWEEN MEAN AND VARIATES	SQUARE OF DIFFERENCE

61	4.05	16.4025	<i>Mean</i> = 56.95
61	4.05	16.4025	
61	4.05	16.4025	$\sigma = \pm 11.17$
61	4.05	16.4025	
C			
62	5.05	25.5025	<i>Coefficient of variability</i>
63	6.05	36.6025	= 19.44
67	10.05	101.0025	
71	14.05	197.4025	<i>Probable error of single</i>
75	18.05	325.8025	determination = $\pm .45$
20) 1139.	157.40	20) 2494.9500	
56.95		124.7475	

The *group* contains 20 *variates*. The *mean* is the average of the variates, or 56.95. The *median* in this series lies between the two middle variates and is therefore 60. There are two *quartiles*, the lower being 54 and the upper 61.5. The difference in magnitude between the quartiles and the median indicate that the variates are not grouped closely about the median. This is also evident on inspection. This hypothetical series was chosen to illustrate functions and terms. Under actual experimental conditions, the data collected would not make ordinarily such a uniform series of figures.

The mean and the median do not coincide; that is, the curve has skewness, or is asymmetrical. The *mode* or most frequently appearing figure is 61. It is of greater significance than the *mean*, since it repre-

sents the most probable event because of the number of times it was found.

The difference between the mode (61) and the median (60) is 1. This is less than twice the difference between the median (60) and the mean (56.95), which is 3.05. If it were more than twice 3.05, it would indicate that the variates were not evenly grouped about the modal point, a fact which in such a small series of figures would be also evident upon inspection.

The *standard deviation* is found by obtaining the square root of the quotient obtained by dividing the sum of the squares of the variate deviations from the mean by the number of variates. In the example given,  $2494.25 \div 20 = 124.74$ , the square root of which, or  $\sigma$ , is  $\pm 11.17$ .

The *coefficient of variability* is  $100 \times \frac{11.17}{56.95} = 19.44$ . The *probable error* of a single variate is found by taking the square root of the figure obtained by dividing the sum of the squares of the deviations by the number of variates minus one, and multiplying the result by a constant  $\pm .6745 \sqrt{\frac{2494.95}{20-1}} = \pm .45$

For a further consideration of the mathematics involved, etc., the appended bibliography may be consulted.

### HEREDITY VERSUS ENVIRONMENT

How much of our physical and mental make-up is due to heredity (nature) and how much to environment (nurture) is one of the much-discussed problems. It seems evident to students of biology that by far the overwhelming factor in our organization is set and definitely fixed at our birth. Heredity appears to be the overshadowing influence

of first and prime importance. Herbert Spencer well said that "inherited constitution must ever be the chief factor in determining character." Environment may influence the individual, but apparently has small and slow power of propagating itself for good; great and rapid power for evil. That is, the hereditary transmission of acquired characters is denied, but the transmission of defects of organization, such as insanity, deaf mutism, the consequences of syphilis, alcoholism, and other vices, are fully recognized. Atavism, reversion, and mutations must not be regarded as instances of the hereditary transmission of acquired characters in the biological sense. The tendency of the artificially bred strains of the civilized human races to revert and deteriorate has already been emphasized.

Despite the teachings of biology we are convinced that life is inexorably conditioned by its environment. The environment of today is the heredity of tomorrow. Jordan states that "among the factors everywhere and inevitably connected with the course of descent of any species variation, heredity, selection, and isolation must appear; the first two innate, part of the definition of organic life; the last two extrinsic, arising from the necessities of environment, and not one of these can find leverage without the presence of the others." In the present state of our knowledge, while we are convinced that heredity plays the major rôle, we are by no means prepared to deny the influence of environment.

## IMMUNITY GAINED THROUGH INHERITANCE

Immunity to disease is either natural or acquired. Natural immunity is inherited through successive generations of a species or a race. Acquired immunity, like other acquired characters, is not inherited as a "unit character" in the sense of Mendel. Thus, there has been little variation in our natural power to resist most infections, such as tuberculosis, yellow fever, plague, smallpox, cholera, tetanus, measles, scarlet fever, diphtheria, and so on through a long list, although these diseases have doubtless afflicted the human species through untold ages. The fluctuating virulence of some infections is a matter of common knowledge, and is doubtless due to many variable factors. In a few well-known instances a certain amount of tolerance or resistance has been gained and perhaps transmitted through succeeding generations by a process of the survival of the fittest. Thus, syphilis is much less virulent now than it was during the great pandemic of the sixteenth century. The resistance which the natives enjoy to malaria in badly infected quarters of the globe is largely acquired as a result of early infections, and this increased resistance is perhaps partly transmitted by a weeding out of the very susceptible. See Section IV, Chapter I.

## CHAPTER III

### THE HEREDITARY TRANSMISSION OF DISEASE

We are now prepared to discuss more in detail the hereditary transmission of disease. The question whether disease is ever transmitted hereditarily or not rests somewhat upon our conception of disease; that is, whether it is an entity, a reaction, or a "unit character." The process itself, of course, cannot be transmitted, but the potentiality of it may be involved in some peculiarity in the organization of the germ plasm. This may be, and often is, transmitted through successive generations. In the limited sense in which the word "heredity" is used in biology and in the limited sense in which the word "disease" is used in pathology, there may be no inherited diseases, but this appears to be a quibble of words or a matter of definitions. While we are not familiar with the intimate processes concerned, we are certain that many abnormal conditions of mind and body are transmitted. Some of them follow the Mendelian principles.

Formerly a large number of diseases were regarded as transmissible, but the list has been revised and restricted as a result of recent studies. The reappearance of a diseased condition in successive generations does not prove that it has been transmitted or even that it is transmissible. This mistake has been made with tuberculosis and other infections.

Lack of completeness vitiates most of the statistics bearing on heredity in relation to human diseases. Even in the case of clearly inherited diseases there are very few pedigrees sufficiently complete for the study of the applicability of Mendelian and other laws of heredity.

Sometimes the disease itself is not transmitted, but a tendency to the disease is transmitted. This will be discussed again.

Some unit characters as well as certain diseases are transmitted hereditarily, but limited to one sex; that is, the disease or condition appears in one sex only, although transmitted by the other. This remarkable sort of inheritance, known as sex-linked inheritance, occurs when the male parent is characterized by the absence of some character of which the determiner is typically lodged in the sex (x) chromosome. A striking feature of this sort of heredity is that the trait appears only in males of the family, but is not transmitted by them; it is transmitted, however, through normal females of the family. Examples of this sort of heredity are hemophilia, color-blindness, also multiple sclerosis, atrophy of the optic nerve, myopia, ichthyosis, and muscular

atrophy. The explanation is the same in all cases of sex-linked heredity. The abnormal condition is due to the absence of a determiner from the male sex chromosome.

The diseases, defects, and conditions believed to be transmitted hereditarily are discussed in the following pages. Some of these diseases, malformations, and defects of organization follow Mendel's law. It is probable that other diseases, tendencies, and characters are transmissible, but the subject has only recently been placed upon a scientific basis, and it will require careful and prolonged observation to establish the facts. It is often difficult to determine whether the disease itself or a tendency to the disease has been transmitted in any particular case, and, further, it is often difficult to decide whether an individual has inherited or acquired his affliction.

The transmissible defects which are of principal concern to the human species are the defects of organization of the central nervous system. It is important to remember that the defects of the nervous system do not necessarily propagate just the same defects in the succeeding generations. Thus, an epileptic does not necessarily beget epileptics; epilepsy, insanity, degeneracy, feeble-mindedness, alcoholism, drug addiction, and other stigmata may arise as the result of deficiencies of various kinds of forebears.

Defects such as harelip, cleft palate, cervical fistula, spina bifida, etc., are not true instances of hereditary transmission of specific characters. They rather represent an inherited deficiency in developmental vigor. These defects for the most part represent the failure of parts to unite during embryological development; in other words, the failure of embryological clefts to close normally. Such deformities, as well as clubfoot, web fingers, and other acquired or congenital deformities or disfigurations, are not, as a rule, transmitted.

Some practical problems of great importance arise from our knowledge of the hereditary transmission of disease and defects. A man or woman who intends marrying is now more than justified in carefully examining the personal and medical histories of the family of his or her intended mate. It is not only possible to foretell the color of the eyes, the nature of the hair, and other Mendelian characters in the future offspring, but it is also possible to foretell, with mathematical precision, the chances of transmitting defects, such as insanity, epilepsy, degeneracy, feeble-mindedness, deaf-mutism, color-blindness, migraine, and other nervous disorders, as well as hemophilia, polydactylism, brachydactylism, albinism, and other stigmata. In any doubtful case it may be well to consult a student of heredity, for it is possible to foretell with precision in certain cases which characters will and which will not be transmitted.

To illustrate the precision with which the characters of offspring may be predicted in the best studied cases, we need only refer to the color of the eyes. Two parents with pure blue eyes will have only blue-eyed offspring, for they both lack the brown pigment which determines the color of the iris. Similarly, if the hair of parents be flaxen, this may be taken as evidence of the absence of a hair-pigment-determiner in the germ plasm, and the offspring will have flaxen hair. For the same reason parents with lack of curliness or waviness of hair will have only straight-haired children. See table on the following page.

In determining whether transmissible characters are apt to reappear in successive generations or not we must know whether these characters are positive or negative, that is, whether they are due to the presence or absence of determiners.<sup>1</sup>

**Inbreeding** may be hazardous for reasons that are well understood. The marriage of cousins will be evidently hazardous if the objectionable hereditary characters are dominant, for in this case the danger is plain; if the characters are recessive the danger is specially unfortunate, because of unexpected outcroppings in the offspring. Inbreeding tends to secure homozygous combinations, and this brings to the surface latent or hidden recessive characters. Cross breeding brings together differentiated gametes which, reacting on each other, produce offspring of greater vigor. On the other hand, continued cross breeding only tends to hide inherent defects, not to exterminate them; inbreeding only tends to bring them to the surface, not to create them. It is not, therefore, correct to ascribe to inbreeding by intermarriage the creation of bad racial traits, but only their manifestation. Further, a racial stock which maintains a high standard of excellence under inbreeding is certainly one of great vigor and free from inherent defects (Castle).

The influence of isolation and the results of *consanguineous marriage* are well brought out when we study certain localities. Thus, consanguinity on Martha's Vineyard results in 11 per cent. deaf mutes and a number of hermaphrodites; in Point Judith, 13 per cent. idiocy and 7 per cent. insanity; in an island off the Maine coast the consequence is "intellectual dullness"; in Block Island, loss of fecundity; in some of the "Banks" off the coast of North Carolina suspiciousness and an inability to pass beyond the third or fourth grade of school; in a peninsula on the east coast of Chesapeake Bay the defect is dwarfness of stature; in George Island and Abaco (Bahama Islands) it is idiocy and blindness (G. A. Penrose, 1905). There is thus no one trait that results from the marriage of kin; the result is determined by the specific defect in the germ plasm of the common ancestor.

<sup>1</sup>We do not yet know all the unit characters in man, and it is impossible to foretell which of them are due to positive determiners and which to the absence of such.

## INHERITED CHARACTERS IN MAN

*From Castle—Genetics and Eugenics*1. **Blending**

General body size, stature, weight, skin-color, hair-form (in cross-section, correlated with straightness, curliness, etc.) shape of head and proportions of its parts (features).

2. **Mendelian**

	<i>Dominant</i>	<i>Recessive</i>
Skin and hair.....	Dark. Spotted with white. Tylosis and ichthyosis (thickened or scaly skin).	Blonde or albino (probably multiple allelomorphs). Uniformly colored. Normal skin.
	Epidermolysis (excessive formation of blisters). Hair beaded (diameter not uniform).	Normal skin. Normal hair.
Eyes.....	Front of iris pigmented (eye black, brown, etc.). Hereditary cataract. Night-blindness (when not sex linked). Normal.	Only back of iris pigmented (eye blue). Normal. Normal. Pigmentary degeneration of retina.
	Brachydactyly (short digits and limbs). Polydactyly (extra digits). Syndactyly (fused, webbed, or reduced number of digits). Symphalangy (fused joints of digits, stiff digits). Exostoses (abnormal outgrowths of long bones). Hereditary fragility of bones.	Normal. Normal. Normal. Normal. Normal.
Kidneys.....	Diabetes insipidus (excessive production of urine). Normal.	Normal. Alkaptonuria (urine black on oxidation).
	Huntington's chorea. Normal.	Normal. Hereditary feeble-mindedness.

3. **Mendelian and Sex-Linked**

(Appearing in males when simplex, but in females only when duplex.)

<i>Dominant</i>	<i>Recessive</i>
Normal.	Gower's muscular atrophy.
Normal.	Hemophilia (bleeding).
Normal.	Color-blindness (inability to distinguish red from green).
Normal.	Night-blindness (inability to see in faint light).

4. **Probably Mendelian but Dominance Uncertain or Imperfect**

Defective hair and teeth or teeth alone, extra teeth, a double set of permanent teeth, barelip, cryptorchism and hypospadias (imperfectly developed male organs), tendency to produce twins (in some families determined by the father, in others by the mother), left-handedness, otosclerosis (hardness of hearing owing to thickened tympanum).

5. **Subject to Heredity, but to What Extent or How Inherited Uncertain**

General mental ability, memory, temperament, musical ability, literary ability, artistic ability, mathematical ability, mechanical ability, congenital deafness, liability to abdominal hernia, cretinism (due to defective or diseased thyroids), defective heart, some forms of epilepsy and insanity, longevity.

**The Microbic Diseases.**—It seems a confusion of thought to the student of heredity to speak of the inheritance of any microbic disease. At one time the hereditary transmission of microbic diseases was generally believed. Now we know that, in the true sense of the term, no infectious disease is transmitted hereditarily—for even in the case of syphilis the *Treponema pallidum* is carried in the germ or sperm as a foreign body. Tuberculosis at one time was considered as transmitted, but we now know that this occurs so seldom that the popular pamphlets are entirely justified in denying it entirely.

Children are sometimes born with smallpox, measles, and other infections; these are not true instances of heredity, but cases of congenital transmission.

**Congenital Transmission.**—Prenatal infection is not a true instance of inheritance. Microbic diseases may be acquired by infection through the placenta during the fetal period. The placenta is a better filter for some infections than for others. Thus, anthrax and tuberculosis of the mother are rarely transmitted to the fetus, while there is great liability in the case of syphilis. The fetus *in utero* may take smallpox, measles, and other infections, but these instances are more properly spoken of as congenital than inherited.

We must remember that to be inherited on the part of the offspring or transmitted on the part of the parents, biology includes only those characters or their physical bases which were contained in the germ plasm of the parental sex cells (Martius); or, as Verco says, "what operates on the germ after the fusion of the sex nuclei, modifying the embryo, or even inducing an actual deviation in the development, cannot be spoken of as inherited. It belongs to the category of early acquired deviations which are, therefore, frequently congenital."

**Hereditary Transmission of a Tendency to a Disease.**—While the disease itself may not be transmitted, a tendency to a disease, known as a diathesis, may be transmitted through successive generations. A person may inherit a small bony structure, a poor musculature, "weak" lungs, susceptible mucous membranes, or an abnormal amount, distribution, or development of lymphoid structures, etc. In fact, we are not all born equal, and most persons have some vulnerable structure or organ which is commonly spoken of as their "weak point." In many cases this *locus minoris resistentiae* is transmitted as a defect in structure or function.

Davenport has collected the health records and other characteristics furnished for over two hundred families by members of the families concerned. He finds certain definite facts in the behavior of some of the commoner diseases. As an example of the inheritance of a general weakness in an organ he cites the case of the mucous membranes. Thus, in one family the principal diseases to which there was liability were located in the mucous membranes of the nose, throat, and bronchi.

In another family the center of susceptibility was more specific, being nearly confined to the nose and throat. In another family the weakness was in the ear; in another the lungs; in another the skin; in one family the kidneys were the seat of incidence, etc.

The examination of the health pedigrees of a number of families impresses one by the fact that the incidence of disease is not always haphazard, for in any large family the various causes of death do not occur in the proportions given in the census table for the population as a whole.

**Tuberculosis.**—We know that tuberculosis is never transmitted hereditarily, and is seldom contracted congenitally. The reason that tuberculosis runs in a family is twofold: (1) an inherited predisposition to the disease, and (2) increased chances of infection, especially during infancy. Just what the tendency or predisposition is, is not well understood. We do know, however, that the predisposition is not so great but that it may be overcome; the infection may be avoided and the disease prevented. No one is born doomed to die of tuberculosis.

It is now perfectly plain that the principal reason why tuberculosis runs in families is the close association between the infected and well members of the family, which increases the chances of infection and re-infection.

All persons inherit the power of resisting tuberculosis in varying degree. The inborn immunity is not marked in any case; in some individuals it is quite feeble. The border line between immunity and susceptibility to tuberculosis in the human species is delicately balanced and may readily be overturned (see page 177).

**Syphilis.**—Syphilis and the consequences of syphilis are transmitted from parent to offspring—"even unto the third and fourth generation." The transmission of the infection itself is *congenital*; the transmission of the consequences of syphilis, such as defectives, etc., may follow the laws of heredity.

The methods of transmission may be briefly summarized as follows: (a) The husband has syphilis. He infects his wife: and she infects the embryo. Experience indicates that this is the usual method of transmission, and that the wife is often infected soon after marriage. The treponemata circulating in the blood stream of the mother apparently penetrate the placenta with ease, and enter the blood stream of the child. The child naturally has no trace of a chancre, so that we have here another indication of the possibility of syphilis d'emblée.

It is now generally believed that paternal transmission directly to the fetus is impossible. Treponemata have been demonstrated in the seminal fluid of syphilitics, and numerous innocent marital infections have been transmitted by means of infected spermatic fluid by husbands who thought they were healthy.

(b) The wife alone has syphilis and infects the child in the same manner as in (a). It is fairly obvious that in any case of congenital syphilis, the mother is certainly infected, and the father is usually, but not necessarily infected.

A syphilitic father may beget an apparently healthy child, even when the disease is fresh and full-blown. On the other hand, in very rare instances a man may have syphilis when young, undergo treatment, and for years present no signs of disease, and yet his first-born may show very characteristic lesions. The closer the begetting to the primary sore the greater the chance of infection. A man with tertiary lesions may beget healthy children. As a general rule, it may be said that with judicious treatment the transmissive power seldom exceeds three or four years.

*Collé's and Profeta's Laws.*—Collé, in 1837, stated that apparently normal women bearing syphilitic children do not contract syphilis when exposed to that infection. (This is also called Baumès' law.) Profeta's law states that a child showing no taint but born of a woman suffering from syphilis will not become infected even though suckled by its mother. Exceptions to both Collé's and Profeta's laws are recorded. The explanation of these so-called laws was that the mother was immune in Collé's law and the baby in Profeta's law. We now know, however, that both the mother and the baby under these circumstances are infected with spirochetes but do not manifest clinical symptoms of the disease. The apparent immunity in both instances is due to the fact that superinfection does not occur. See page 63.

Concerning the results of congenital syphilis, we have the following possibilities: (1) The infection causes a cessation of development and abortion. (2) The fetus grows, but is born before the normal expiration of intra-uterine life (premature births). (3) The fetus goes to term, but is born dead (stillbirths). (4) The child is born at term living, but with unmistakable signs of syphilis, and dies shortly. (5) The child may show no symptoms of syphilis at birth, but a few weeks later develop typical symptoms. It may die, or as the result of treatment, may live. Syphilis causes death in 80 per cent. of those congenitally infected. It is a still greater tragedy in the 20 per cent. who survive. (6) The child shows no symptoms of syphilis for weeks, months or possibly years, the disease being latent, and becomes manifest in some cases as late as twenty-eight years in the tertiary form (so-called syphilis hereditaria tarda). (7) The child may be puny, weak, susceptible to infections, underweight, and lack stamina—in short, a runt. This may occur without obvious manifestations of the disease.

See article on Syphilis, pages 55 to 67.

**Cancer.**—It will probably be a long time before the final word can be said concerning the influence of heredity in cancer.

Maude Slye<sup>2</sup> has studied the question of inheritance of cancer in mice and concludes that cancer is not inherited, but that a tendency to produce cancer under the right stimulus is transmitted from generation to generation. The stimulus seems to be over-irritation at the point where the cancer arises. Cancer can be bred in and out of strains of mice at will. Cancer is transmitted rather as a tendency to occur from a given provocation, an over-irritation. The elimination of over-irritation in one of cancer ancestry should materially lower the rate. Further, the eugenic control of mating so that cancer shall not be potential in both parents would also very materially decrease the incidence of human cancer. Tyzzer and Little have also shown that a tendency to cancer is transmitted in experimental laboratory animals.

It seems clearly established that certain chronic irritating agencies may induce cancer, at least in susceptible persons. The irritation may be actinic, thermal, chemical, or mechanical. Thus we have Röntgen ray epitheliomas, Kangri skin cancer of India, the epitheliomas on the arms of paraffin makers, chimney-sweep's cancer of England, and also the brand cancer of cattle. Each of these present definite and distinct lesions; each has a constant etiology, clinical course, and pathology. To this same group also belongs the buyo cheek cancer of the Philippine Islands caused by chewing buyo, the irritating agent of which appears to be lime.

The prevailing misconception that cancer is a hopeless and incurable disease is not entirely correct. Cancer at first appears to be a local disease, and therefore curable if detected in time and removed.

Cancer causes upward of 80,000 deaths a year in the United States. It is chiefly a disease of adult life. Eighty-three per cent. of deaths from cancer occur at the age of forty-five and over. In the United States, cancer causes one death in every eight women, and one in every fourteen men over forty years of age. The excessive mortality from cancer in women is due to the prevalence of cancer of the breast and generative organs.

Cancer may be inoculated in experimental animals, but the disease is not a contagious or infectious one, in the sense that it is communicable under natural conditions from person to person. The supposed "cancer houses," "villages," or "streets" do not bear the light of critical examination. The "virus" is probably not a microörganism, but the cancer cell itself, which undergoes unrestrained and riotous proliferation. In other words, the parasite is the cancer cell itself, and the cancer cell comes from a normal preëxisting epithelial cell.

The Commission on Cancer of the Medical Society of the State of Pennsylvania found that 39 per cent. of the superficial cancers and 46 per cent. of the deep-seated cancers are preceded by a precancerous condition or a chronic irritation. In other words, in almost one-half of the

<sup>2</sup>*Jour. Med. Res.*, 1915, Vol. XXXII, p. 168.

patients that are sent to the surgeon with a fully developed cancer there has been a previous condition which might have been removed and cancer might not have developed. Superficial cancers frequently exist for a year and a half before they come to the surgeon.

Warthin,<sup>3</sup> from studies of a long series of cases, believes that a marked susceptibility to carcinoma exists in the case of certain family generations and family groups. This susceptibility, he thinks, is frequently associated with a marked susceptibility to tuberculosis and also with reduced fertility. The multiple occurrence of carcinoma in a family generation practically always means its occurrence in a preceding generation. The family tendency is usually more marked when carcinoma occurs in both maternal and paternal lines. Family susceptibility to carcinoma is shown particularly in the case of carcinoma of the mouth, lip, breast, stomach, intestines, and uterus. In a family showing the occurrence of carcinoma in several generations there is a decided tendency for the tumor to develop in the breast of the youngest generations. In this case the tumors often show an increased malignancy. Levin's study of cancerous fraternities leads him to believe that the cancerous members correspond very closely to the Mendelian percentage of members with recessive unit characters in a hybrid generation. Levin concludes that resistance to cancer is a dominant character whose absence creates a susceptibility to cancer. While some of Warthin's cases show a family history suggesting this form of inheritance, others indicate a progressive degenerative inheritance, that is, the running out of a family line through the gradual development of an inferior stock, particularly as far as resistance to tuberculosis is concerned.

Statistical studies indicate that cancer is on the increase.<sup>4</sup> This, however, is questioned. At least it is necessary to know the age distribution and many other factors before we can say that cancer is on the increase. The death rate from cancer in the United States rose from 63 per 100,000 in 1900 to 81.6 in 1917. These are census figures and may not represent the real situation.

**Leprosy** was formerly regarded as one of the inherited infections, but leprosy is not transmitted. The children of lepers born out of leper districts, in England or the United States, for example, never inherit it. The disease is contracted after birth, as tuberculosis and other microbic diseases are contracted.

**Deaf-mutism.**—Deaf-mutism is due to a great variety of causes, but in different individuals of the same family the chances are large that it is

<sup>3</sup> Warthin, A. S.: *Heredity with Reference to Cancer*. *Arch. Int. Med.*, Chicago, Nov., XII, 5, pp. 485-612.

<sup>4</sup> Frederick L. Hoffmann, "The Mortality from Cancer Throughout the World." Also *Bull. 8, Amer. Soc. for the Control of Cancer*. Cancer Pamphlets I to X, published by the American Medical Association. Popular articles on the subject.

due to the same defect. This defect is frequently recessive, that is, hidden in the normal children. Two such normal children who are cousins but from deaf-mute stock tend to have about one-fourth of their offspring deaf-mutes. The proportion of deaf offspring is thrice as great among cousin marriages as among others. The conclusions of Fay, based on extensive statistics, deserve to be widely known. "Under all circumstances it is exceedingly dangerous for a deaf person to marry a blood relative, no matter whether the relative is deaf or hearing, nor whether the deafness of either or both or neither of the partners is congenital, nor whether either or both or neither have other deaf relatives besides the other partner."

**Albinism.** — Albinism belongs to a class of cases resulting from the absence of a character or quality—in this instance the absence of a pigment determiner. Two albino parents have only albino children. Normal offspring of an albino and a pigmented parent may transmit the albinic condition.

Albinism is an extreme case of bloneness, all pigment being absent from skin, hair, and eyes. The method of inheritance resembles that of eye color. When both parents lack pigment, all offspring are likewise devoid of pigment. When one parent only is an albino and the other is unrelated, then the children are all pigmented. Whenever pigmented parents have albino children, the proportion of

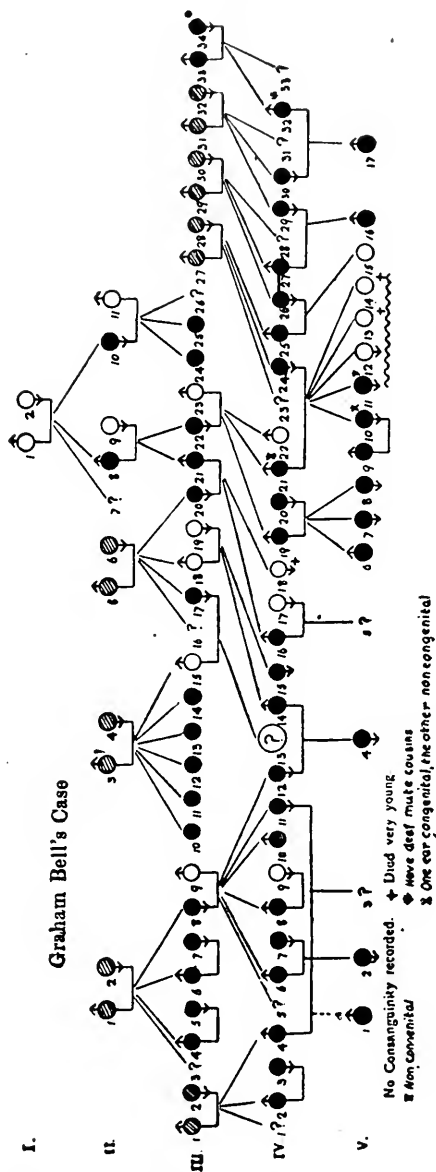

FIG. 70.—FAMILY HISTORY SHOWING DEAF-MUTISM. From "Treasury of Human Inheritance."

the albinos approaches the ideal and expected Mendelian proportions—25 per cent. Davenport points out that albinos may avoid albinism in their offspring by marrying unrelated pigmented persons. Pigmented persons belonging to albinic strains must avoid marrying cousins, even pigmented ones, because both parents might, in that case, have albinic germ cells and produce one child in four albinic. Albino communities, of which there are several in the United States, are inbred communities, but not all inbred communities contain albinos.

**Color-blindness, or Daltonism.**—Color-blindness, or daltonism, is a condition probably not localized in the eyes, but due to some defect in the central nervous structure. It is transmitted hereditarily. Color-blindness is much commoner in men than in women. A color-blind man, however, does not transmit color-blindness to his sons; the daughters, also, are themselves normal, provided the mother was, yet the daughters transmit color-blindness to half their sons. A color-blind daughter could be produced apparently only by the marriage of a color-blind man with a woman who transmits color-blindness, since the daughter, to be color-blind, must have received this unit character from both parents, whereas the color-blind son receives the character only from his mother; that is, the condition is sex-linked.

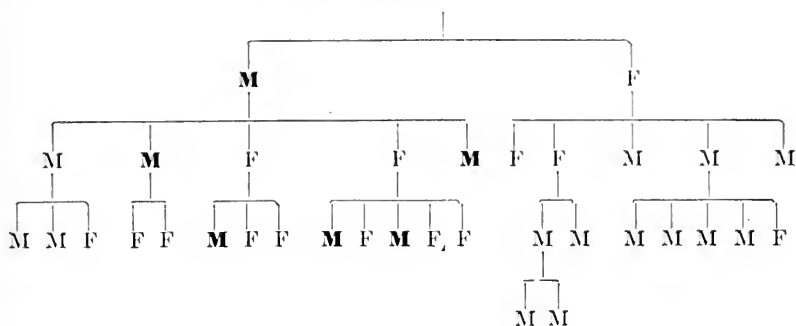

Color-blindness is apparently due to a defect in the germ cell—absence of something normally associated there, with an X-structure which is represented twice in women, once in men.

The following interesting family history, studied by Horner, shows the hereditary persistence of color-blindness and its transmission to male offspring through normal females.

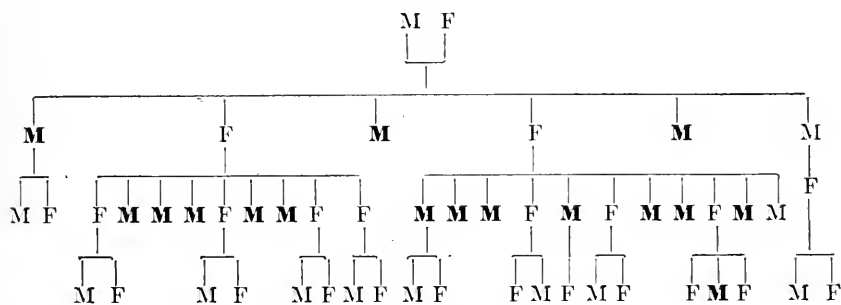

The following pedigree of a family containing color-blind members was worked out by Dr. Rivers among the Todas, an Indian tribe:

**Hemophilia.**—Hemophilia is a condition in which the blood does not coagulate properly, and those having this condition may bleed to death from minute wounds. It is transmitted hereditarily and is largely confined to males, although transmitted by normal females. It is one of the best instances of an hereditary character, sex-linked.

(Bold-faced type indicates bleeders.)

The foregoing case, given by Klebbs, is instructive in showing how the tendency, though transmitted through daughters, finds expression only in the males, and in illustrating first a diffusion and then a waning of the peculiarity (Thompson).

**Gout.**—It is known that gout runs in families, but just what the predisposition is that favors this condition of deranged metabolism is not known. During four centuries one family history showed that out of 535 gouty subjects 309 had a family taint—about 60 per cent. In another family out of 156 cases 140 had a family taint, about 90 per cent. Statistics show that in from 50 to 60 per cent. of all cases the disease existed in the parents or grandparents. It seems clear that some predisposing factor may be transmitted hereditarily, but in any individual case it is not always plain how much is due to heredity and how much is acquired.

**Brachydactylism.**—A typical example of an abnormality transmitted hereditarily is that of brachydactylism, or short-fingeredness, a condition in which each digit comprises only two phalanges—the fingers are

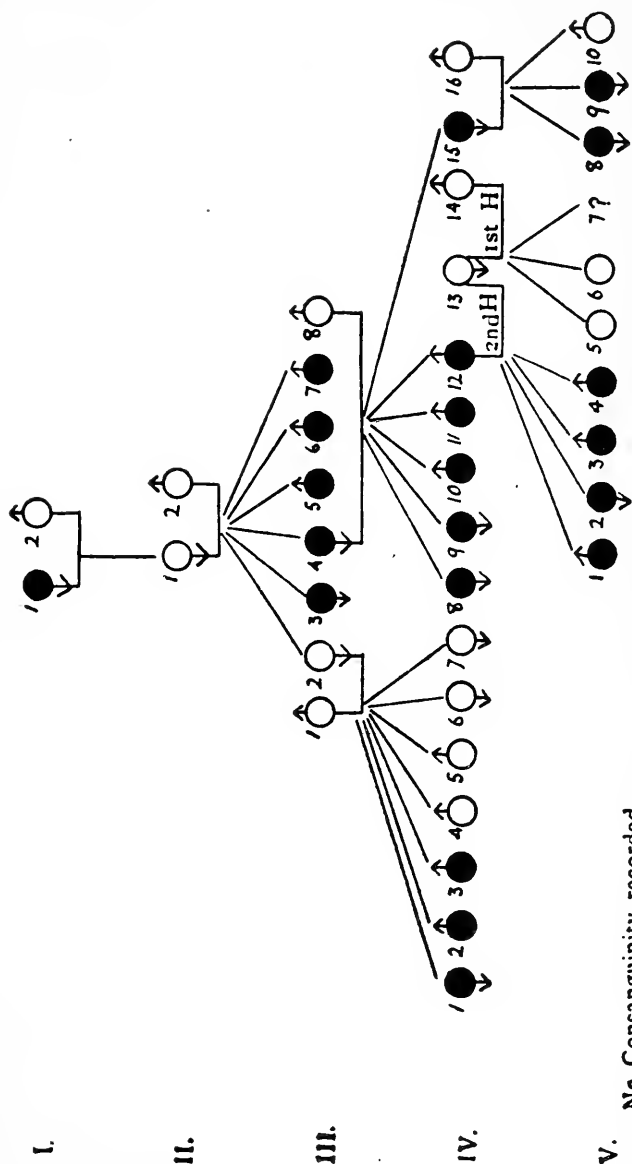

FIG. 71.—FAMILY HISTORY SHOWING POLYDACTYLISM.  
Smith and Norwell's case. From "Treasury of Human Inheritance."

all thumbs. This condition seems to be due to an inhibition of the normal growth process, that is, normality implies entire absence of the determiner that stops the growth of the fingers in the brachydactyl.

Thus, a brachydactyl person married even to a normal person will beget 100 per cent. or 50 per cent. abnormalities, according to circumstances; but two parents who, though derived from brachydactyl strains, altogether lacking the determiner which inhibits the growth of the fingers may have only normal children.

According to Punnett, brachydactylism is a good example of a simple Mendelian case. It behaves as a simple dominant to the normal; that is, it depends upon a factor which the normal does not contain. The recessive normals cannot transmit the affected condition whatever their ancestry. Once free, they always remain free, and can marry other normals with full confidence that none of their children will show the deformity.

**Polydactylism.**—Polydactylism is a condition in which there are supernumerary fingers or toes. This is a defect which may be transmitted through successive generations. Other defects of the fingers and toes are transmitted in accordance with the Mendelian expectation.

**Fragilitas Ossium.**—Fragilitas ossium, or osteopsathyrosis, a weakness of the long bones, may arise from a number of pathological conditions affecting the bones. But the typical fragilitas ossium or brittle bones runs through families. Davenport and Conrad<sup>5</sup> have shown that the factor which determines the deficient bone formation is a dominant one. Different degrees of the condition are transmitted true to type. Thus in some families the slightest pressure results in fracture; in other families the bones are fairly resistant. The association of blue sclerotics with brittle bones has often been pointed out; the condition of blue sclerotics also appears to be a dominant trait.

**Myopia.**—Myopia can hardly be called a disease in the strict sense, being a structural defect in the focusing power of the optical apparatus. It seems that the structural peculiarity which leads to short-sightedness is transmitted.

**Cataract.**—Bateson and others have collected pedigrees in which cataracts run in families. Presenile cataract especially appears to be transmitted hereditarily. The transmission is as a rule direct, the skipping of a generation being unusual. Cataract is also favored by various constitutional diseases, such as diabetes, Bright's disease, and diseases of the vascular system. Exposure to the light and heat ray from glowing coals, or flashes of electricity produce opacities of the lens. Injury, and prolonged eye strain are responsible for many cataracts.

**Retinitis Pigmentosa.**—Retinitis pigmentosa is a degenerative disease of the retina which is transmitted hereditarily. Normals may carry the disease, so that two normal cousins from retinitis stock may have

<sup>5</sup> Davenport, C. B., and Conrad, H. S.: "Hereditary Fragility of Bone," *Proc. Nat. Acad. Sc.*, 1915, i, 537.

offspring with retinitis. A large percentage of cases of retinitis come from consanguineous marriages.

**Diabetes Mellitus.**—Hereditary influences seem to play an important rôle in diabetes mellitus, for cases are on record of its occurrence in many members of the same family. Thus, out of 104 cases of diabetes mellitus 22 had a family taint—about 20 per cent. Naunyn obtained a history of diabetes in 35 out of 201 private cases, but in only 7 of 157 hospital cases.

**Orthostatic Albuminuria.**—Orthostatic albuminuria occurs in boys more commonly than girls. These are often the children of neurotic parents, and have well-marked vasomotor instability. Defects or peculiarities in the filtering apparatus in the kidneys may arise as a germinal variation and be handed on from generation to generation. Under conditions which may mean nothing to normal subjects this defect in the kidney may find expression in active disease. In this case, as in gout, it may not be proper to speak of the disease itself being transmitted hereditarily, but the tendency to deviate is so transmitted.

**Alcoholism.**—Alcohol as well as lead and other poisons can damage the germ cell of the male in such a way as to express itself by defective offspring (*Rauschkinder*, or Jagchildren). It is a common observation that among the offspring of drunkards are many cases of unhealthy, insane, and criminal types. The disastrous results may be manifested by nervous disorders, varying from hyperexcitability to dementia; or as debility and lack of developmental vigor expressed, for instance, in infantilism, want of control, imbecility, or as structural abnormalities, especially of the head and brain. The results are so varied, they suggest that what is inherited is general rather than specific. Thus, the offspring of alcoholic parents are not necessarily predisposed in any one particular direction, except that the nervous system is most liable to be affected. They may be epileptic, idiotic, insane, etc. On the other hand, it is necessary to recognize that what may be inherited is not the result of alcoholism, but rather the predisposition which led the parent to become alcoholic. This is clearly illustrated in cases where the parent did not acquire the alcoholic habit until after the children were born. Clouston observes that "it is not the craving for alcohol that was inherited, but a general psychopathic constitution in which the alcoholic stimulus is an undue stimulus and the mental control deficient." See page 430.

**Migraine.**—That migraine is transmitted hereditarily is indicated from the family histories of those suffering with this affection.

Buchanan<sup>6</sup> found from a study of 1,300 persons suffering with migraine that it is transmitted in the Mendelian ratio. His studies establish the hereditary nature of the affection.

<sup>6</sup> *Med. Record*, Nov. 13, 1920, p. 807.

**Anaphylaxis, or Food Idiosyncrasies.**—Experimental evidence, as well as family histories, clearly indicates that hypersusceptibility to certain foods, such as egg, shellfish, strawberries, tomatoes, etc., is transmitted hereditarily through several generations. The transmission is sometimes specific and limited to one particular food.

**Hay fever** and other anaphylactic conditions such as asthma, angio-neurotic edema, etc., usually show a family history of "idiosyncrasies" of various sorts. See page 605.

**Epilepsy.**—Brown-Séquard showed conclusively that artificially induced epilepsy in the guinea-pig is transmissible. The statistics collected for man give from 9 to over 40 per cent. of cases in which heredity is an important predisposing cause. Gowers gives 35 per cent. for his cases. In the Elwyn cases 32 of the 126 gave a family history of nervous derangement of some sort, either paralysis, epilepsy, marked hysteria, or insanity. Thom's<sup>7</sup> study of 1,536 epileptics at the Monson State Hospital (Mass.) would make it appear that epilepsy is transmitted directly from parents to offspring less frequently than we have heretofore been led to believe.

Chronic alcoholism in the parents is also regarded as a potent predisposing factor in the production of epilepsy. Echeherria has analyzed 572 cases bearing upon this point, and divided them into three classes, of which 257 cases could be traced directly to alcohol as the cause, 126 cases in which there were associated conditions, such as syphilis and traumatism, 189 cases in which alcoholism was probably the result of the epilepsy. Figures equally strong are given by Martin, who, in 150 insane epileptics, found 83 with a marked history of paternal intemperance. Of the 126 Elwyn cases in which the family history of this point was carefully investigated, a definite statement was found in only 4 of the cases (Osler).

**Huntington's Chorea.**—Huntington's chorea is frequently inherited. The disease is known as chronic hereditary chorea. It was described by Lyon in 1863, who traced the disease through five generations. Huntington in 1872 gave the three salient points in connection with the disease, viz.: (1) its hereditary nature; (2) association with psychical troubles; and (3) late onset between the thirtieth and fortieth year.

Huntington's chorea is a typical dominant trait. The normal condition is recessive; in other words, the disease is due to some positive determiner. Persons with this dire disease should not have children, but the members of normal branches derived from the affected strain are immune from the disease. This disease forms a striking illustration of the principle that many of the rarer diseases of this country can be traced back to a few foci, even to a single focus; certainly in this case many of the older families with Huntington's chorea trace back to

<sup>7</sup> *Boston M. and S. Journal*, CLXXIV, 16, April 20, 1916, p. 573.

the New Haven colony and its dependencies and subsequent offshoots (Davenport).<sup>8</sup>

FIG. 72.—FAMILY HISTORY SHOWING HUNTINGTON'S CHOREA.  
Last generation incomplete. Data from Hamilton.

**Friedreich's Disease—Hereditary Ataxia.**—This disease resembles locomotor ataxia, although differing from it in several essential particulars. It begins in childhood and usually occurs in a family having

<sup>8</sup> *Am. Journ. of Insanity*, Oct., 1916, LXXIII, No. 2, p. 195.

other members of the family affected with the same disease. There are curious forms of incoördination and loss of knee-jerk, early talipes equinus, scoliosis, nystagmus, and scanning speech. The affection lasts

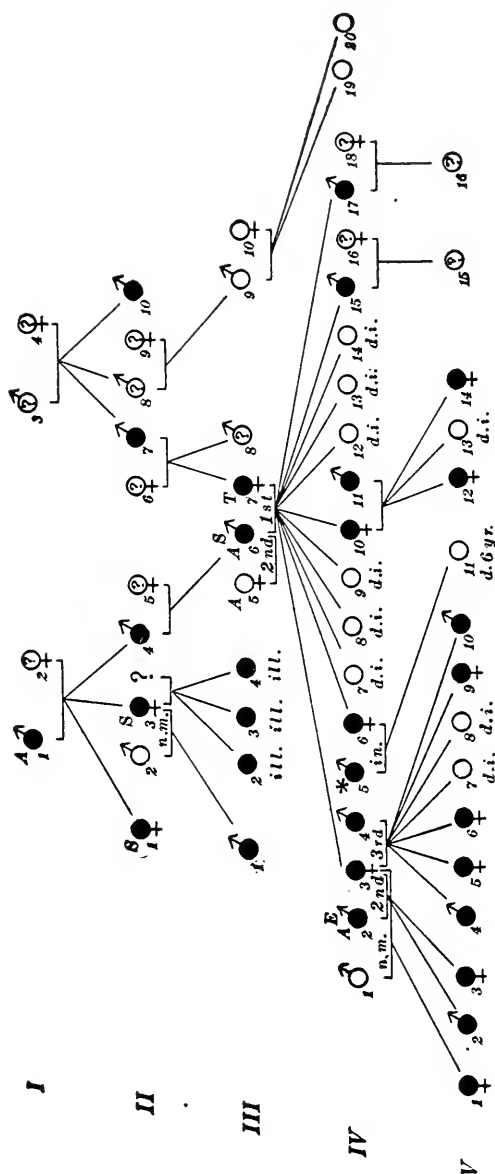

FIG. 73.—FAMILY HISTORY SHOWING FEEBLE-MINDEDNESS.

Data from Goddard. A, alcoholic; E, epileptic; d. i., died in infancy; ill., illegitimate; in., incest; \*, same individual as III, 6; n. m., not married; S, sexual pervers; T, tuberculous.

for many years and is incurable. In 1861 Friedreich reported six cases of this form of ataxia in one family. Since then it has usually been observed to be a family disease, and is, therefore, assumed to be trans-

mitted hereditarily. The eugenic teaching in this affection, according to Davenport, is that normal members of the affected fraternities should marry only outside the strain. Whether all cases of ataxic offspring of one normal parent are derived from consanguineous marriage is still uncertain and warrants hesitation in advising the marriage of any ataxic person.

**Mental Deficiency.**—This term includes imbecility, idiocy, feeble-mindedness and psychopathic inferiority, etc. In this class we have one of the best examples of a pathological condition transmitted by inheritance. Davenport believes that imbecility is due to the absence of some definite simple factor, on account of the simplicity of its method of inheritance. Two imbecile parents, whether related or not, have only imbecile offspring. Davenport states that there is no case on record where two imbecile parents have produced normal children.

Dr. H. H. Goddard, of the Training School for Feeble-Minded, at Vineland, N. J., has studied the ancestry of children in the Vineland institution and has found almost without exception a history of feeble-mindedness for several generations. Dr. Goddard's remarkable study of the Kallikak family has already been referred to. In this instance he traced the ancestry of a 22-year-old girl through about 1,100 individuals as far back as the Revolutionary War. Similar studies are being carried out in other institutions and always with similar results. The subject is fully discussed on pages 425 and 615.

**Insanity.**—Insanity is a general term comprising many different conditions. No general statement can, therefore, be made except that certain forms of psychoses are undoubtedly transmitted through successive generations. It is safe to say that heredity is responsible for more cases of mental diseases than any other single cause. Mental diseases are rare in persons free from ancestral taint, except as the result of wounds or toxic influences.

Practically all the statistics accumulated on insanity have limited value to the student of heredity, because they do not give numerical records of the sane members of the families of the insane. The subject is fully discussed in Section II, page 421.

## SECTION V

### FOOD

#### CHAPTER I

##### GENERAL CONSIDERATIONS

Foodstuffs fall naturally into two great divisions: (1) those derived from the animal kingdom, and (2) from the plant kingdom. The animal foods are much more apt to convey infections or to possess injurious properties than foods derived from plant life. Of the animal foods meat and milk are the chief offenders. Water ordinarily is not classed as a food because it passes unchanged through the body and hence does not furnish energy. Water is discussed in Section VIII.

It is often said that there is "death in the pot." This is a clever aphorism, but a gross exaggeration. The statement is misleading, for it implies frequent and serious injury due to food, whereas food poisoning is relatively rare and seldom fatal. There is no danger in clean food, little in fresh food, and still less in thoroughly cooked food.

The hygienic conscience of the people has been aroused, and a demand is being established for clean, fresh, wholesome foodstuffs. The separation of the producer and the consumer and the demands of large cities have made these sanitary reforms eminently necessary. The pure food laws, the meat inspection act, the milk ordinances, and the local surveillance over markets, provision shops, dairies, food-handlers, etc., are all part of the general movement to obtain a reasonably decent and safe food supply.

People should be educated to demand flesh from healthy animals, cut up and handled in a careful manner by butchers free from disease, and to demand garden truck grown in clean dirt and not in soil polluted with human excrement. Food must be guarded in transportation and purveyed in markets and shops so as to be protected from flies, rats, dust, and unnecessary human contact.

The prophylactic and therapeutic uses of food are growing subjects. It is only necessary to point out the importance of diet in the prevention and treatment of beriberi, scurvy, pellagra, rickets, tuberculosis, diabetes, acidosis, nephritis, arteriosclerosis, gout, rheumatic affections,

disorders of metabolism, dyspepsia, gastric ulcer, infantile diarrheas, and many other affections.

The proper amount, variety, and quality of food is one of our most important preventive measures; in fact, the vigor and success of a nation rests fundamentally upon its diet. Diet is influenced by many circumstances, such as availability of foods, economic status, habits and prejudice, knowledge and education, etc. Instinct is not always a safe guide. Finally, diet may lower the standard of public health in subtle ways, for there are probably many degrees of malnutrition not recognizable except in their effects on the individual over a long period of time. Diet may make or mar public health.

**How Foods May Be Injurious to Health.**—Food may affect health in a great variety of ways:

(1) *Natural Poisons.*—Foods may be naturally poisonous, as in the case of certain mushrooms, some fish, or the alkaloids in various species of plants.

(2) *Animal Parasites.*—Foods may convey animal parasites, such as trichina and tapeworms. These parasites, as a rule, occur as ante-mortem infections in the flesh of the food animal. Plant foods too may carry the eggs or larvae of various animal parasites, some of which are capable of developing in the human body.

(3) *Plant Parasites.*—Foods usually contain bacteria. Both animal and vegetable foods may convey bacteria pathogenic for man. The harmful varieties are more often found in animal foods than upon plant foods. Milk often contains tubercle bacilli, or streptococci; sometimes diphtheria bacilli, or other pathogenic microorganisms. Typhoid bacilli may be conveyed in oysters, or on celery, water cresses, etc.

The common cause of food infection, or “food poisoning” as it is called, is the Gaertner bacillus (*B. enteritidis*) or one of the other closely allied members of the colon-typhoid group (pages 699, 700).

(4) *Toxins.*—Poisonous substances may develop in the food as a result of bacterial activity. The only example we have in this class is botulism.

(5) *Putrefactive Poisons.*—This includes the class of so-called ptomains, or decomposition products of protein. “Ptomain poisoning” is hypothetical, and has not been demonstrated. The term is a misnomer, and its popularity unfortunate. *Infected* food rather than *decomposed* food is apt to cause acute gastro-intestinal attacks.

(6) *Special Poisons.*—Foods may contain special poisons, as, for example, solanin in sprouted potatoes, or ergot in rye. There is a substance in buckwheat, actuated by light, which may cause serious injury owing to photodynamic action.

(7) *Accidental Poisons.*—A great variety of substances may find their way into food, either through accident or intent. They include

arsenic, lead, caustic alkalies, acids, alkaloids, adulterants, insect powders, etc.

(8) *Amount*.—Injury is caused by eating too much or too little food; thus, an excess of food predisposes to obesity and perhaps to arteriosclerosis and degenerative lesions of the liver and kidneys; an insufficient amount undermines health. Undernutrition in children is common. War edema is due to underfeeding.

(9) *Composition*.—An unbalanced diet affects growth, vigor and health. Certain faulty diets lead to beriberi, scurvy, rickets, pellagra and other deficiency diseases. Goiter is due to lack of iodine in water, food, or both. An excessive fatty diet in infants leads to acidosis. An excess of protein favors putrefactive changes. An excess of carbohydrate food favors fermentation. Highly spiced and stimulating diets are irritating both to the digestive tube and organs of excretion: drinking too little water is a common dietetic error.

(10) *Digestion and Metabolism*.—Foods otherwise wholesome may be injurious on account of faulty digestion or disturbances of metabolism. The common causes of such troubles are eating too fast, improper mastication, eating when fatigued or overheated, injudicious combinations, especially unripe fruits or vegetables, containing raw or partly cooked starch, etc.

(11) *Anaphylaxis*.—Certain persons have an idiosyncrasy to particular foods. This occurs most commonly with sea-food, but also takes place with strawberries, eggs, tomatoes, milk, oatmeal, and a great variety of substances. Many forms of protein in foods produce symptoms resembling anaphylaxis in persons who are sensitized; whereas the foods themselves may be entirely wholesome.

## THE USES OF FOOD

The two ultimate uses of all food are to supply the body, (1) with materials for growth or renewal, and (2) with energy or the capacity for doing work. The potential energy received in a latent form stored in the various chemical combinations in foods is liberated as kinetic or active energy in two chief forms, heat and motion. Force is the manifestation of energy, and the force developed by a healthy man may be measured in foot pounds. A *foot pound* is the amount of energy expended or force required to lift mechanically a weight of one pound to a height of one foot.

The work of an average man is calculated at about 2,000,000 foot pounds per diem. This may exceptionally be increased to 3,000,000 foot pounds. Ordinarily less than one-fifth of the total energy of the body is expended in motion, and more than four-fifths in heat production.

**Caloric Value of Food.**—The total intake of energy into the body is derived from food plus the oxygen of the inspired air. The total output of energy is computed from: (1) the heat of combustion of the unoxidized ingredients of the urine and feces; (2) the energy liberated as body heat; and (3) the energy of external muscular work, or the work of the voluntary muscles.

Whether alimentary substances are burned outside of the body or oxidized within the body, the resulting waste products are similar. Food is good fuel if it fulfills two conditions, viz.: easy assimilation and complete combustion.

It is not sufficient to know merely the amount and caloric value of the coal fed to a furnace, and subtract therefrom the amount of unconsumed ash. We must know how much of the heat generated has been *utilized*. The food must burn completely and without smoking.

The ordinary articles of diet cannot be utilized without vitamins. The importance of these "unknown dietary factors" in promoting growth, as well as in the *utilization* of foods is a recent discovery.

Calorie for calorie foods are not interchangeable so far as nutritive value is concerned. The food calorimeter further gives no indication of digestibility. Concentrated calories may be quite as worthless for human physiologic purposes as a piece of anthracite coal.

Two methods may be employed to study the energy-producing power of food in the body: (1) a careful and prolonged study of subjects who are allowed to follow their usual vocations, but whose food and excreta are carefully measured and analyzed; (2) the shorter method of enclosing a man for a brief period, not exceeding a few days, in a cabinet known as a calorimeter.

The unit of measurement is the *Calorie*, which is the amount of heat required to raise one kilogram<sup>1</sup> of water from 15° to 16° C. This equals 3,100 foot pounds, or approximately the heat required to raise the temperature of one pound of water 4° F. *Fuel value* is a term denoting the total number of Calories derived from a gram or pound of any given food substance if it is completely combusted within the body. The fuel values are calculated for a given food by the factors of Rubner as follows:

4.1 Calories per gram of either protein or carbohydrate.

9.3 Calories per gram of fat.

Atwater and Bryant compute the food factors as 4 calories per gram for proteins and carbohydrates and 8.9 for fats, in a mixed diet. C. F.

<sup>1</sup>This is the large Calorie. The small Calorie is the amount of heat required to raise one gram, instead of one kilogram of water from 15° to 16° C. The large Calorie is the one used in studies of food and metabolism.

Langworthy gives the fuel value of the three chief classes of nutrients as follows:

1 pound of protein yields .....	1,860 Calories
1 pound of fats .....	4,220 Calories
1 pound of carbohydrates .....	1,860 Calories

The following are the quantities which are generally accepted at the present time as a sufficient daily diet for a man of average weight, doing a moderate amount of muscular work:

	Weight in Grams	Weight in Oz.	Energy Value in Calories
Protein .....	100	3.75	400
Fat .....	100	3.75	900
Carbohydrates .....	500	18.00	2,000

Total energy value, 3,300 Calories

Of course the energy value must be greater if more work is done, and conversely, so that we may have such figures as these:

Light work .....	3,000 Calories
Moderate work .....	3,500 Calories
Heavy work .....	4,000 or more Calories

During the World War the U. S. ration in the field was:

Protein .....	158 grams
Fat .....	200 "
Carbohydrates .....	514 "

Energy value, 4,600 Calories.

From a chemical standpoint foods are oxidized or burned to simpler compounds during the process of digestion and metabolism within the body. Food is, therefore, fuel. The oxygen to feed the flame is mainly furnished by the inspired air. Exercise and active breathing of pure fresh air is essential and one of the best stimuli for complete metabolism. It is the common experience of all persons that digestion and the utilization of foods are favorably promoted by life in the open air.

The value of a diet does not depend wholly upon its caloric value and vitamin content. The importance of flavors, spices, and the preparation of food depends not alone upon the application of chemistry and physics, but also upon physiology.

Perhaps the greatest use of the art of cooking is in the preparation of dishes attractive to the palate and other senses. Appetite plays a

very important part in digestion, stimulating the secretion of gastric juice, which is produced in the stomach ready for the reception of food.

### CLASSIFICATION OF FOODS

Foods are classified in various ways, but no classification is complete. They may be divided into groups, according to their physical properties, their source, their composition, and their function, or the rôle which they perform in the animal body, and their biologic properties.

**Physical Properties.**—Foods are classed in accordance with their general physical properties first into solid, semisolid, and liquid foods; secondly, into fibrous, gelatinous, starchy, oleaginous, crystalline, and albuminous foods. Foods are also classed as foods, beverages, and condiments. Roughage is cellulose and other indigestible residue.

**Sources.**—Foods may be classed as to their source primarily into (a) animal, (b) plant, and (c) mineral.

Animal foods consist of meat, fowl, fish, shellfish, crustaceans, insects and their products (honey), eggs, milk and its products, animal fats, gelatin.

The plant foods are subdivided into seeds, roots and tubers, leaves; also cereals, vegetables proper, fruits, sugar, gums, vegetable oils and fats.

The minerals are mainly calcium, potassium, sodium, chlorine, fluorine, iodine, magnesium, phosphorus, iron, sulphur, etc. They are chiefly taken as part of the constituents of animal and plant foods—except sodium chloride, water and its dissolved salts.

**Chemical Composition.**—The simplest chemical classification possible is that advocated by Liebig, who was the first to suggest a really scientific definition of foods. He grouped all foods into two classes: nitrogenous and non-nitrogenous. Each of these classes contains food materials from both the animal and vegetable kingdoms, although the majority of the animal substances belong to the nitrogenous and the majority of the vegetable preparations to the non-nitrogenous group.

Nitrogenous foods contain proteins and include gelatinoids and albuminoids, substances which resemble albumin. They consist chiefly of the four elements: carbon, oxygen, hydrogen, and nitrogen, to which a small proportion of sulphur and phosphorus is usually joined. The nitrogenous foods were regarded by Liebig as containing plastic elements; that is, they are essentially tissue builders or flesh formers. The non-nitrogenous group Liebig called respiratory or calorific foods, because their function in the body is largely to furnish fuel to maintain animal heat. It is now known that the non-nitrogenous foods supply energy for muscular action, hence they are also called force

producers, to distinguish them from the nitrogenous or tissue builders. This is a convenient distinction, but it must not be held too absolutely, for the tissue builders are used as force and heat producers as well.

**Composition and Function.**—Foods are now ordinarily classed as: (1) proteins, (2) carbohydrates, (3) fats, (4) condiments, (5) inorganic salts, and (6) vitamins.

1. *Proteins.*—Proteins build tissue and repair waste; to a less extent they serve as fuel to yield energy in the forms of heat and muscular power. Meats, milk, eggs, and a few seeds such as the pea and bean are very rich in protein, the cereal grains contain less of this food substance, whereas the tubers and vegetables, especially in the fresh condition, contain but very little. We now know that *proteins are not all of equal food value*. We have excellent, good or poor food proteins for the formation of body proteins in growth. Hence, the quality as well as the quantity of proteins is important.

Soon after 1900 the researches of Emile Fischer revealed the great variation in the composition of proteins from different sources. Most proteins can be resolved into about 17 simple digestion products called amino-acids, and the proportions in which these are present in the protein molecule varies greatly in proteins from different sources. All or nearly all of these digestion products appear to be indispensable constituents of an adequate diet. All natural foods contain several proteins, as the extensive and valuable studies of Osborne have shown. The proteins of any single foodstuff may be regarded as biologically complete, but their nutritive values differ greatly, depending upon the yield of the several amino-acids which can be obtained from them. Definite quantities of at least four of the amino-acids—lysine, cystine, tryptophan and tyrosine—are essential for the nutrition of rats.

Casein is a complete protein because it contains all of the 17 or 18 amino-acids necessary to rebuild human protein; hence, milk is the best source of protein. Meat protein is also of good quality, but it is not an economical food. The cellular organs such as liver and pancreas are good sources of protein; this is also true of the leafy plants, although the amount is comparatively small. Proteins of seeds are of poor quality because they contain only a few of the amino-acids necessary to rebuild human protein. It is possible by combinations of incomplete proteins to obtain satisfactory dietary results. The great difference in the biologic values of the proteins from different sources is one of the outstanding results of modern research in nutrition.

Although a diet containing 100 grams of protein per day is usually recognized as satisfactory there is evidence that, for healthy individuals, this quantity may be unnecessarily large. Chittendon has long advocated a low protein diet. On the other hand, Atwater's standard as the minimum protein ration is 125 grams.

2. *Carbohydrates*.—The starchy or carbohydrate foods are represented by the cereals, the tubers, such as potatoes, the sugars of the cane, beet, fruits, etc., and glycogen in flesh.

3. *Fats*.—Fats or oily foods are represented by butter, olive oil, cotton-seed and other oils, the fat of meat, the oil of nuts and seeds. All vegetables contain more or less oily substances. The fats as well as the carbohydrates serve as fuel to yield energy in the form of heat and muscular power.

Certain fats contain a vitamin which is indispensable, whereas other fats do not contain this dietary essential. This vitamin, known as "fat-soluble A," is abundant in the fat of milk, eggs, and is generally found in other fats of animal origin, and also in leafy plants. Little or none is found in lard and oils of plant origin (page 670). Fats, then, do not all have the same dietary value.

The chief worth of fat lies in the ease with which it is stored, especially in the connective tissue. Although carbohydrate is also stored, in the form of glycogen, a kind of starch, in the liver and muscles, this takes place only to a limited extent. We notice that both these food-stuffs, fat and carbohydrate, enable a store of reserve material to be kept for use when required to give energy. Fat has a higher energy value, weight for weight, than carbohydrate.

A very practical value of fat consists in its use in cooking. Very few attractive dishes can be made without it, and it is a physiologic principle that food should be eaten with relish.

4. *Condiments*.—Among the condiments are classed: spices, such as pepper, mustard, cinnamon, cloves, etc.; also coffee, tea, and alcoholic beverages.

5. *Inorganic Salts*.—Mineral matter or ash performs an important service in forming bone and assisting in digestion and metabolism. These substances are ordinarily not classed as foods; however, life cannot be maintained without them. This applies also to the vitamins.

Common organic or vegetable acids, such as citric from lemons and oranges, tartaric from grapes, malic from apples, etc., usually exist in combination with the bases, calcium, sodium, potassium, etc., when derived from fresh vegetables and fruits. They are indispensable articles of food, for when absorbed they form carbonates, which aid in maintaining the alkalinity of the blood.

If calcium phosphate is deficient in the food of the young, growing infant, the bones are poorly developed and so soft that they yield to the strain of the weight of the body and become bent, as occurs in rickets. Of all foods, milk is the best source of calcium, as it contains this element in abundance and in utilizable form. Milk, however, is deficient in iron, and therefore this fact must be taken into account when used as a sole article of diet for growing children or adults.

Lack of iodine in the diet leads to goiter.

Lack of inorganic salts in the food impoverishes the coloring matter of the red blood corpuscles on which they depend for their power of carrying oxygen to the tissues, and anemia and other disorders result. An ash-free diet soon causes serious symptoms.

The ordinary American diet, consisting of cereals, bread, meat, and potatoes is rather lacking in mineral constituents, especially calcium.

Longworthy gives the following as the estimated amount of mineral matter required per man per day:

Phosphoric acid ( $P_2O_5$ ).....	3	to 5	grams
Sulphuric acid ( $SO_3$ ).....	2	to 3.5	"
Potassium oxid.....	2	to 3	"
Sodium oxid.....	4	to 6	"
Calcium oxid.....	0.7	to 1.0	"
Magnesium oxid.....	0.3	to 0.5	"
Iron .....	0.0006	to 0.012	"
Chlorid .....	6	to 8	"

6. *Vitamins*.—Vitamins promote growth and favor the utilization of food. On account of their importance, a brief summary of our knowledge on this subject follows:

### VITAMINS

Vitamins are "accessory factors" in the diet necessary for growth and metabolism. They are "unknown dietary factors" essential to life. Vitamins are remarkable in that exceedingly small amounts produce extraordinarily great results—in this respect resembling enzymes. Their chemical nature is not known. Vitamins are produced in the plant world even by simple unicellular cells such as yeast. They cannot be elaborated nor stored by man or other animals. Growth, nutrition and utilization of food therefore depend upon the daily intake of vitamins. In this sense, we live a hand-to-mouth existence.

Eyckman,<sup>2</sup> in 1897, showed that polyneuritis could be induced in fowls by restricting them to a diet of polished rice, and that a diet of undecorticated rice would cure fowls of this condition. In 1907, Fraser and Stanton<sup>3</sup> showed that the alcohol extracts of rice polishings would relieve experimental polyneuritis. In 1911, Funk<sup>4</sup> took up the problem and showed that pressed yeast, hydrolyzed with 20 per cent. sulphuric acid for 24 hours retained its property of curing polyneuritis when given to birds, from which he concluded that in yeast and in rice polishings there was present a chemical entity of a nitrogenous basic nature which

<sup>2</sup> *Arch. f. path. Anat., etc.*, Berl., 1907, 148, 523; *Arch. f. Hyg.*, München and Berl., 1906, 58, 150.

<sup>3</sup> *Lancet*, London, 1910, 733; *Philippine J. Sc.*, Manila, 1910, 5, B, 55.

<sup>4</sup> *J. Physiol.*, 1911, 43, 395; *J. Physiol.*, 1912, 45, 75.

he called "vitamin." The antineuritic property of this substance was soon confirmed, but its chemical nature was not established.

It soon became evident that from the standpoint of chemical nomenclature, the term vitamin was in some respects ill chosen. Hopkins<sup>5</sup> suggested the term "accessory food substances," and later McCollum<sup>6</sup> suggested the specific terms "Fat-soluble A" and "Water-soluble B" to identify the "unknown dietary factors."

Despite the fact that subsequent study has shown vitamins are not amines, the term is now established by usage.

Osborne and Mendel,<sup>7</sup> in 1911, reported a series of experiments involving the study of the effect of feeding purified proteins and mixtures thereof with other purified nutriment. They called attention to the peculiar effect upon growth induced by "protein-free milk." A little earlier, Hopkins had called attention to the fact that the addition of milk to purified food mixtures produced results out of all proportion to the caloric value of the milk. In 1912, McCollum and Davis<sup>8</sup> showed that butter fat and egg yolk contain something that stimulates growth and is absent in lard and olive oil. Later, McCollum and his associates showed that this principle "Fat-soluble A" is present especially in milk, eggs and leafy vegetables. Drummond<sup>9</sup> recently suggested that the antiscorbutic vitamin be classified as "Water-soluble C."

There are probably a large number of vitamins, but only three are clearly recognized:

(1) "*Fat-Soluble A*" is associated with certain fats, and is especially abundant in milk, butter, egg yolk, the fat of glandular organs, such as the liver and kidneys, cod liver oil, and also in the leaves of plants. The seeds of plants contain less, and products derived from the endosperm of the seed are very poor in this substance. Thus, such foods as bolted flour, degerminated corn meal, polished rice, starch, glucose and the sugars from milk, cane and beet, are practically free of this vitamin. It is also practically absent from lard and the fats and oils of vegetable origin and non-pigmented fats generally.

Milk and the green leaves of plants can therefore be regarded as "protective" foods, and should never be omitted from the diet. Milk is a better protective food than are the leaves, because it contains a larger amount of this vitamin.

The specific result of a lack of a sufficient amount of this vitamin in the diet is the development of xerophthalmia. The eyes become swollen so badly that they are opened with difficulty or not at all. The cornea becomes inflamed, and unless the missing dietary essential is

supplied, blindness speedily results. These results have been obtained for the most part in rats fed upon an experimental diet. Mellanby's observations on dogs show a relation between Fat-soluble A and rickets. The results are accepted by the Medical Research Committee of Great Britain, and it is now regarded by many as an established fact that the fat-soluble vitamin is synonymous with the antirachitic vitamin. Hess and Unger state that although this vitamin may be a factor in the etiology, it is not the dominant factor in its pathogenesis.

(2) "Water-Soluble B" promotes growth, and its absence induces

polyneuritis (beriberi). This vitamin is widely distributed in all forms of natural foods and can be isolated in a concentrated, but not in a pure form, by extraction with alcohol or water. It is found in animals, seeds, leaves and tubers, but it is never associated with fats or oils of either animal or plant origin. Our ordinary foods all contain several times the amount of "Water-soluble B" which is necessary for the maintenance of growth and health in animals.

(3) "Water-Soluble C" is important in connection with scurvy. Our knowledge concerning this vitamin is still incomplete.

Whether each deficiency disease, such as pellagra, rickets, scurvy, etc., is caused by the absence or lack of a specific vitamin, is not yet established.

It is now well demonstrated that with the mixed diets ordinarily employed in Europe and America there is no such thing as a "vitamin" problem.

The table on page 671 shows the occurrence of vitamins in a large number of substances.<sup>10</sup> In the absence of any satisfactory quantitative measurement for vitamin, it is impossible to indicate absolutely the amounts of any type in a given source. The system adopted aims to show the relative abundance. (+ + +) indicates abundance; (+ +) sufficient to require no supplement in feeding experiments where the source indicated is the sole supply; (+) present, but not in sufficient quantity to be relied upon as the sole source; (—) means absent or so little as to be negligible; (?) undetermined.

The question of the effect of heat, acid and alkali upon vitamins is still unsettled. In a recent article<sup>11</sup> Drummond has published the following summary of our present knowledge of the subject:

Stability	Vitamin		
	Fat-Soluble A	Water-Soluble B	Antiscorbutic C
To temperature.....	Stable at 100° C.; probably stable at 140° C.	Comparatively stable at 100° C.; slowly destroyed at 120° C. and above.	Gradually destroyed above 50° C.; rapidly destroyed above 80° C.
To alkali.....	Stable in cold; possibly in hot.	Slowly destroyed in cold; rapidly in hot.	Rapid destruction even in cold.
To acids.....	Probably stable.	Comparatively stable.	Comparatively stable below 50° C.

Most observers agree that long boiling with acids does not harm "Water-soluble B" (antineuritic) vitamin, and Osborne and Mendel, also McCollum and others hold that "Fat-soluble A" found in butter-fat will sustain the temperature of live steam without destruction. On the

<sup>10</sup> *Absts. Bacteriology*, III, No. 6, Dec., 1919, p. 313.

<sup>11</sup> *Lancet*, London, 1918, II, 482.

other hand, alkalis seem to be destructive to most vitamins. The anti-scorbutic vitamin (type C) is much more heat labile than the "A" or "B," and is apparently diminished in milk and in some fruits and vegetables by drying.

The inevitable sequence to the discovery of the vitamins was the tendency to attribute to them specific relationship with many diseases of unknown origin. Thus, polyneuritis, pellagra, sprue, marasmus, scurvy, rickets, disturbances of growth, etc., presented problems which it was hoped the study of vitamins might solve. Workers in each field have endeavored to secure evidence of the relation of vitamin to the particular disease. The results vary with the disease studied. Pellagra and sprue, for example, have not yet been demonstrated to be linked definitely with vitamin activity. Growth, polyneuritis, xerophthalmia and rickets have been shown to be directly related to the activity of the "A" or "B" factors. Marasmus has shown some evidence of connection with the two vitamins and scurvy has been linked with the "C" vitamin.

Extensive studies on the nutritive efficiency of various diets and on the specific behavior of the dietary factors "A" and "B" have shown that *both* are essential to the normal growth of such experimental animals as rats, swine, fowls, etc., and by analogy or, in a few cases by direct experiment, to human animals. Hess has recently questioned the necessity for the "A" type in the development of human infants.

Many microscopic organisms require or utilize vitamins for growth and development, such as yeasts, meningococcus, influenza bacillus, typhoid bacillus, gonococcus, pneumococcus Type I, streptococcus hemolyticus, B. diphtheriae, B. pertussis, soil organisms, etc.

## THE AMOUNT OF FOOD

**Excessive Amounts.**—The amount of food required varies greatly with conditions. In civilized communities, where cooking is a fine art, the number and variety of food preparations are so great that the appetite is often stimulated beyond the requirements of the system, and consequently more food may be eaten than is necessary or desirable to maintain the best bodily health and vigor. Gluttony results in overdevelopment and overwork of the digestive apparatus; the stomach and bowels become enlarged; the liver is engorged, and a predisposition is established to degenerative changes, fatty heart, etc. Overeating is also supposed to favor high blood pressure and arteriosclerosis. The quantity of food required to maintain the body in vigor varies with the climate and season, clothing, occupation, work, and exercise, the state of individual health, age, sex, and body weight.

Both overeating and overdrinking may be temporary or chronic.

When chronic it may lead to obesity, gout, lithemia, oxaluria. It is very certain to cause congestion of the liver and the condition known as "biliousness," in which the stomach and intestines are engorged, constipation results, the tongue is heavily coated, the bodily secretions are altered in composition, the urine especially becomes overloaded with salts, the liver becomes congested, and, finally, the nervous and muscular systems are affected, which result in the production of headache and feelings of fatigue, lassitude, drowsiness, and mental stupor. An excess of protein favors putrefactive changes in the intestinal tract; an excess of carbohydrates tends to fermentation; an excess of fat leads to acidosis, especially in babies. Excessive starch and sugars in the diet may serve as an exciting cause of diabetes, especially in persons who might otherwise go through life without developing the disease.

**Insufficient Food.**—Starvation or asitia is a term which technically applies to the lack of sufficient food for the maintenance of the body, while inanition means the lack of the assimilation of food by the tissues. When food is completely withheld, life cannot be prolonged beyond six or ten days in the majority of instances. Professional fasters have gone 41 days without anything but water. If food is withheld suddenly, the sensation of hunger gradually increases, becomes extreme, lasts for two or three days, and slowly disappears. It is accompanied by a gnawing pain in the epigastrium, which is relieved on pressure. The pain may disappear, but it is followed by a sensation of extreme weakness or faintness, which is both local in the stomach and general throughout the body. Even though the pain disappears, the sensation of hunger may occasionally reassert itself, when all food is withheld, until death, or until the subject becomes insane or unconscious.

Hunger is not always a reliable guide to the need of the system for food. Some dyspeptics are always hungry and eat more than they can digest. A habit of rapid eating does not satisfy the sensation of hunger. More food may be taken than is necessary, because it has not had time to meet the needs of the system before the meal is over. Cannon has shown that the sensations of hunger come and go rhythmically, appearing synchronously with the contractions of the empty stomach.

A reduced diet causes a lowering of basal metabolism, influences the sex instinct and its manifestations. There results a lessening of sex interest and a diminution in procreative power.<sup>12</sup>

**Undernourishment.**—Recent studies have shown that a large percentage of growing children are underweight for their height. From 15 to 40 per cent., and even as high as 60 per cent., of school children have been found to be undernourished. The condition is even more prevalent among the children of the well-to-do, than those of the poor. The causes of undernourishment are (1) physical de-

<sup>12</sup> Miles, *Jour. of Nerv. and Mental Dis.*, 49.3. Mch., 1919.

fects, (2) lack of home control, (3) chronic over-fatigue, (4) improper health habits, and (5) improper diet and food habits. To remedy the condition often requires the coöperation of the parent, the teacher, the physician and the child. See also page 676.

**Famine and Pestilence.**—The statement is frequently made that, when starvation occurs upon a large scale, affecting a community with famine, pestilence is sure to accompany it. Thus, disease has often been rampant in Ireland when the potatoes have failed, and in India when the grain supply has given out. Much of the illness which occurred in the early history of the Crimea was coincident with insufficient food, and it is stated that in the middle ages the ravages of pestilential diseases, such as typhus, smallpox, plague, etc., were always worse in times of general starvation. The history of epochs of famine in siege or otherwise is always accompanied by outbreaks of violence, for hunger begets ill temper, vice, and crime. This has occurred of late years, notably in Athens, Florence, and London, and in Paris during the Commune. There is, however, no very definite relationship between famine and epidemics. The "depressed vitality" caused by insufficient food is not the real cause of epidemics of plague, smallpox, relapsing fever, typhus fever, and other pestilential diseases, sometimes called famine fevers. The reasons for this have been discussed under Immunity.

**War Edema.**—The symptoms of war edema are gravitational dropsy, slow pulse, low blood pressure and polyuria. The condition is associated with prolonged undernutrition, due to lack of calories over a long period of time. The disease is therefore aggravated by cold and exertion and is improved by rest and warmth. Many persons in the war area had a daily ration of only about 1400 calories, consisting mainly of a coarse food, chiefly carbohydrates, very little protein, and almost no fat. All the symptoms can be explained by lack of function of the thyroid gland. Clinically the condition resembles myxedema.

It occurred especially in Germany, Russia, Roumania, but also in other countries during the Great War. When advanced, the symptoms are edema of legs, thighs and genitalia, with some puffiness of the eyelids. In bad cases there is edema also of the chest and abdominal walls. Patients complain of general weakness and pain in the legs. They are usually very apathetic. There is extreme muscular weakness and marked pallor. The whole appearance resembles the condition found in chronic parenchymatous nephritis. Uncomplicated cases are afebrile. With rest in bed and a better ration, improvement slowly takes place.

War edema is clearly the result of underfeeding. The ration responsible was low in protein and almost fat-free. Thus, in Berlin the poorer classes were reduced to a ration containing only about 50 grams of protein per day, which is about half the standard dietary observed in

most civilized countries. The fats were replaced by carbohydrates. The ration was largely vegetable in origin, rich in cellulose, devoid of stimulating properties, and limited in variety. It contained only about 1400 calories.

In addition to war edema, other results were traceable to the restricted diet. Hernias and displacements of internal organs were a frequent consequence of emaciation. Lactation was unsatisfactory among child-bearing women. Gastro-enteric disorders, rickets, and other deficiency diseases occurred, and delayed growth affected the children. Tuberculosis increased its ravages, and decreased resistance to other diseases was noted.

**Underfeeding and Growth.**—Failure to grow according to normal expectations may result from underfeeding, from inappropriate food, or from pathological defects either inherited or acquired. Inborn errors of growth form a special category which falls outside the sphere of nutrition. Retardation of growth due to diets defective in quality rather than quantity will be discussed under "deficiency diseases." Underfeeding per se will retard or suppress growth, but Osborne and Mendel<sup>13</sup> have shown that the capacity to grow is not entirely lost, but is held in reserve until it is exercised. Even when the period of stunting through underfeeding is prolonged beyond the time when growth usually ceases, the institution of a proper diet may result in prompt resumption of growth and apparent completion of its usual cycle.

## UNBALANCED DIETS

**Unbalanced Diets.**—A balanced ration is one that furnishes the optimum condition for the maintenance of vigor and the characteristics of youth; it must promote growth, favor utilization of food and provide for normal reproduction. The science of nutrition has emerged from its simpler beginnings into a complex problem of great intricacies. Attention was first called to the importance of the *chemical* composition of foods, and stress was placed upon the importance of the diet containing protein, carbohydrates and fats. To this was later added the necessity of certain inorganic salts. Now we know that not all proteins are adequate for nutrition, and the fats also have different dietetic values. The *caloric* value of food was next emphasized, but it soon became apparent that many considerations other than fuel value make up a balanced ration. *Biologic* studies then revealed the vitamins, necessary for growth and nutrition.

Some of the factors which make up a balanced diet are: sufficient calories to furnish heat and energy; inorganic salts, especially iron,

<sup>13</sup> *Journ. Biol. Chem.*, XXIII, 439, 1915.

phosphorus and calcium and iodine; abundant quantity and variety of foods containing all the necessary vitamins; some "ballast" or "roughage," that is, undigestible residue such as cellulose. Furthermore, a balanced diet should provide approximately the same fuel value each day. In other words, we should not have a feast and upset our digestion by overeating today, and have a famine tomorrow, but stoke the furnace regularly, according to its needs. Certain edible plants are toxic when used in too large abundance, and this must be avoided in the diet. A balanced diet must also take into account the acid-base equilibrium. Too much acid in the diet draws on alkali reserve, and may reduce resistance to infection and cause injury in other ways. It is plain, then, that a balanced diet depends upon many factors, some of them exceedingly complex. Our only safety lies in a generous ration, varied as possible. A wide variety provides a factor of safety. Growing children especially should have a safe margin both as to quantity and quality, for the science of nutrition is in its infancy.

A balanced diet furthermore consists not only of a liberal consumption of all the essential constituents of a normal ration, but also includes prompt digestion and absorption; also normal metabolism and evacuation of the undigested residue. Such a diet can be attained only by supplementing the seed products, tubers, roots and meats, which constitute the bulk of the diet of man, with milk and the leafy vegetables. Milk and the leafy vegetables are called *protective foods*, because they are rich in vitamins, especially in fat-soluble A. A person who takes a quart of milk a day and some antiscorbutic food will not develop a deficiency disease. Instinct is not always a safe guide for a balanced ration.

## THE DEFICIENCY DISEASES

Unbalanced diets give rise to "deficiency diseases." Thus, a diet lacking the vitamin known as "water-soluble B" gives rise to beriberi; xerophthalmia is brought on by a diet lacking "fat-soluble A"; scurvy is due to the lack of another specific vitamin. Pellagra and rickets are due to dietetic faults, but just what the deficiency consists of has not yet been unraveled. Endemic goiter is caused by lack of iodine in the water or food, or both. War edema is brought about by underfeeding, and especially by a lack of protein. There are other deficiency diseases and conditions which need further study.

The deficiency diseases are mostly chronic and often have a prolonged "period of incubation." In partially unbalanced diets, the threshold of clinical symptoms may never be reached. During this "prodromal" stage, there must be a subtle and doubtless serious effect on health and vigor, resulting perhaps in reduced resistance and impaired efficiency.

*BERIBERI**(Polyneuritis)*

Our knowledge of beriberi<sup>14</sup> is now sufficient to place this scourge of the tropics among the preventable diseases. It is now evident that beriberi is a disease due to an unbalanced diet, deficient in a specific vitamin, "water-soluble B." It is our best known example of a deficiency disease. Most nations where beriberi prevails subsist on a monotonous and one-sided diet, made up largely of polished rice, that is, rice without the pericarp. The disease may be prevented or cured by the administration of rice bran, or other substances containing the specific vitamin.

The particular vitamin associated with beriberi is known as "antineuritic vitamin," or "water-soluble B." A certain amount of this accessory dietary factor must be in the ration in order to permit normal growth of the young and the maintenance of weight and health of the adult animal and man. Its absence from the diet causes polyneuritis and other symptoms of beriberi. This vitamin is very resistant to drying, heat, and other influences, but may be weakened by heating in the presence of an alkali.

Beriberi, or kakke, is a specific form of multiple peripheral neuritis occurring endemically, or as an epidemic, in most tropical or subtropical climates. It is characterized clinically by disturbances of motion, sensation, dropsy, and affection of the heart. The symptoms are attributable to degenerative changes in many of the peripheral nerves, being a toxic neuritis similar in many respects to that produced by alcohol, arsenic, and other poisons, such as the toxon of diphtheria. Three types of the disease are recognized: (1) the paraplegic, or dry; (2) the dropsical, or wet; and (3) the mixed. The course of the disease is uncertain; sudden death owing to involvement of the heart is a common termination. Recovery is frequent and may be complete; it is promoted by change of climate and improvement in the sanitary surroundings, but is dependent upon change to a diet containing antineuritic vitamin.

Many physicians who have studied the subject in Japan, Java, the Philippines, and other countries have long regarded rice as the important cause of the disease. In the prisons of Java the proportion of cases was 1 to 39 when rice was eaten completely shelled, 1 to 10,000 when the grain was eaten with its pericarp. In many places the disease has disappeared when the unshelled rice has been substituted for the shelled.

Eijkman, in 1897, showed that a disease resembling beriberi, characterized by degeneration of the peripheral nerves, may be produced in

<sup>14</sup> Vedder, "Beriberi," Wm. Wood & Son, 1913, contains a complete description and bibliography of the disease.

fowl by feeding them on white or polished rice. These results were later confirmed by Grijns (1900) and Halshoff Pol (1904), but a great impetus was given to the study of the disease by Fraser and Stanton<sup>15</sup> who, in 1909-11, clearly demonstrated that the disease is brought about by a diet of white or polished rice. These investigators took 300 Japanese laborers into a virgin jungle, where they occupied new and sanitary quarters. After excluding the existence of beriberi by a careful examination of each person, they were divided into two parties of equal numbers. One party received polished rice as the staple article of diet, while the other party received undermilled rice with pericarp. In three months beriberi appeared among the members of the party receiving polished rice. When a certain number of cases had been noted, polished rice was discontinued, and thereafter no cases occurred. No sign of the disease appeared among the party receiving undermilled rice. The conditions were then reversed. The party hitherto on undermilled rice were given polished rice, and after a somewhat longer interval beriberi broke out in this group also. This outbreak also ceased on discontinuing the issue of polished rice. Again no sign of the disease appeared among the control party receiving undermilled rice. Place infection and communicability were excluded by transferring individuals suffering from beriberi from one group to the other from time to time. This experiment was later repeated by Strong and Crowell<sup>16</sup> in the Philippines with a similar result.

The same changes in diet which avoid or cure beriberi in man act in a similar manner in respect to polyneuritis in fowl. It has now been established that polished rice causes beriberi if the diet is based almost exclusively on this foodstuff, but that, if a sufficient amount of other things, such as fresh meat and vegetables, are taken with it, the disease is not produced. In the polishing of rice the pericarp or cortical portion of the grain is removed and the embryo is discarded. It is evident that these discarded portions contain some substance (vitamin) essential to a well-balanced ration. It has been found that most of the phosphorus is contained in the pericarp. The amount of phosphorus is a good guide in the selection of a beriberi-preventing rice. In the East, rice is regarded as unsafe if it contains upon analysis a content of less than 0.35 per cent. of phosphorus pentoxid. It is not, however, the absence of the phosphorus which induces beriberi, but the amount of phosphorus, as phosphorus pentoxid ( $P_2O_5$ ) may be taken as an index of the degree to which the rice has been polished.

Funk,<sup>17</sup> in 1911, isolated a substance from rice polishings that pre-

<sup>15</sup> "Studies from the Inst. of Med. Research, Federated Malay States," 1909, No. 10.

<sup>16</sup> *Philippine Journ. Sci.*, 1912, VII, 271.

<sup>17</sup> *Jour. of Physiol.*, 1911, XLIII, 26; also Casimir Funk, *Die Vitamine*, Wiesbaden, 1914.

vents and cures polyneuritis gallinarum. Funk obtained a crystalline organic base ( $C_{17}H_{20}N_2O_7$ ) by precipitation with phosphotungstic acid, and also by silver nitrate in the presence of baryta. The same base was subsequently obtained from yeast and other foods. About 0.02 gram of this substance to pigeons suffering with polyneuritis affects a rapid cure. Funk calls the substance in question "vitamin."

The work of Fraser and Aron, Breaudat and Denier, Dehaan, Heiser, and others leaves little doubt concerning the relation of polished rice to beriberi. Heiser<sup>18</sup> reports that, prior to February, 1910, polished rice was commonly used in the Culion leper colony. The deaths from all cases between February, 1909, and 1910 were 898, of which 309 were due to beriberi. From February, 1910, to February, 1911, unpolished rice was used, and there were 369 deaths, a reduction of over one-half the death rate for the previous year. It is significant that there were no deaths from beriberi during this interval following the use of unpolished rice. Heiser further reports 50 cases of beriberi treated by giving daily 15 grams of rice polishings. Improvement was noticed in all except two very advanced cases. These results have been so striking that the Philippine government has drafted a bill providing for the general use of unpolished rice; that is, rice containing at least 0.4 per cent. of phosphorus as phosphorus pentoxid, and the levying of a tax upon polished rice which makes its sale practically prohibitive. Breaudat and Denier<sup>19</sup> at Saigon, in Indo-China, report good results from the prophylactic use of rice bran. Forty grams are administered daily in the ordinary food. No case of beriberi developed among 49 native soldiers who took bran, while 17.4 per cent. of 311 controls developed the disease.

The prevention of beriberi in the Philippine Islands based upon the rice theory is little short of marvelous. The disease has been entirely eliminated from the Philippine native scouts owing to the reduction in the amount of rice from 20 to 16 ounces, a substitution of undermilled rice for the polished article, and the addition of a legume to the dietary. In 1908 and 1909 there were 600 cases of beriberi annually. In the entire 17 months since the alteration in the ration went into effect there have been but 7 cases of the disease; occasional cases may be expected, owing to disobedience of instructions.

Equally good results of this character are reported by Van Leent,<sup>20</sup> Vorderman,<sup>21</sup> Fletcher,<sup>22</sup> Highet,<sup>23</sup> Theze,<sup>24</sup> Chamberlain,<sup>25</sup> and others.

Infantile beriberi is also common in the Philippines, and may likewise be prevented and even cured with rice bran.

**Rice.**—A grain of rice, after removal from the husk, consists of three parts: (1) an outer layer called the pericarp, which is a very thin membrane. The color of the pericarp varies in different species of rice, from white to yellow, through the browns and reds, to almost black; (2) the middle layer, called the subpericarpal or aleurone layer, which is composed of cubical cells filled with aleurone and fat; it contains very few starch grains. Practically all of the fat, and the greater part of the protein of the grain is confined to this middle layer; the pericarp and

FIG. 74.—SECTIONS THROUGH SEEDS OF RICE (I), WHEAT (II), AND CORN (III), SHOWING THE PROTEIN (P) AND STARCH (S) OF THE SEEDS AND THEIR GERM (E); 1, 2 AND 3, THE SEEDS AS SEEN FROM THE OUTSIDE, NATURAL SIZE.

subpericarp contain practically all the phosphorus, and also all the vitamins, and organic nitrogenous bases. (3) The bulk of the grain, which consists of the innermost portion, is filled with starch granules. The embryo is absent in milled rice.

Rice is first husked between large horizontal revolving stone disks. The chaff is winnowed out. This part of the process chips off only a small part of the pericarp. The grain is then milled by means of a vertical, revolving conical stone, around which is a close fitting metal gauze case. Friction between the stone and the case rubs off the pericarp and the aleurone layer. The dust escaping is called rice polishing or rice bran, which is used in the prevention and treatment of beriberi. In the so-called "highly milled grades" of rice, such as are commonly seen in the markets of the world, all of the pericarp and most of the aleurone layer have been removed. The last process in the treatment of rice is the polishing with buffers covered with long woolled sheep skin.

This removes the dust, and leaves a clean, white grain. Talcum and glucose are often added to give a shiny surface. By undermilled rice is understood rice retaining a large share of the pericarp and aleurone layers.

**Prevention.**—The prevention of beriberi consists in substituting the use of whole rice for the polished grain; also in improving the general quality of the food and in providing for better balanced dietaries, especially adding articles containing vitamins, such as fresh meat, vegetables, milk, eggs and fruit. The prophylactic value of rice polishings added to the ordinary native diet must be borne in mind.

It seems a simple thing to substitute undermilled for highly milled or polished rice, but it will require a long and patient campaign to make a change which is utterly at variance with the economic and social habits of entire nations who have for many years considered the polished rice as the best quality, and generally purchase it by preference. Much may be accomplished through taxation of the highly milled rice, through education, and also, in part, through law.

It should be borne in mind that beriberi may be produced by an unbalanced diet of other starchy substances, such as wheat flour (Little and Strong). Cases have occurred on the coast of Labrador from a restricted diet, consisting largely of wheat flour. Wellmann and Bass<sup>26</sup> produced polyneuritis of fowls with sago in 20 days; boiled white potatoes, 24 days; boiled milled rice, 27 days; cornstarch, 32 days; white flour, 34 days; corn grits, 36 days; oiled sweet potatoes, 38 days; cream of wheat, 39 days; puffed rice, 39 days; macaroni, 40 days. There is no danger of contracting beriberi with the varied diet customary in this country and Europe.

There are certain accessory factors believed to favor beriberi: The disease occurs especially in overcrowded places, such as ships, jails, and asylums; during the hot and moist seasons; and following exposure to wet. These are to be avoided. Europeans living under good hygienic conditions, and enjoying a well-balanced diet, do not contract the disease.

*SCURVY*  
(*Scorbutus*)

Scurvy is a deficiency disease due to some prolonged error in diet, particularly the lack of fresh food in the ration. It is characterized by debility, anemia, a spongy condition of the gums and a tendency to hemorrhages. The lesions occur especially in the bones, the blood vessels and the blood.

Scurvy is undoubtedly due to some fault in the diet, but just what the deficiency consists of is not certain. There is justification to regard it as due to the lack of a special vitamin in the diet, known as "Water-soluble C."

The disease has long been a scourge of sailors and soldiers. Fifty-five of the 143 epidemics analyzed by Hirsch were during hostilities. It affected prisoners and troops in the World War, especially on the eastern front. In Mesopotamia the British troops suffered owing to lack of fresh food. The extent to which scurvy prevailed during the World War is summed up by Hess.<sup>27</sup> It also occurs in the civilian population, sometimes sporadically, often endemic. It is still found in Russia, also among the Hungarians, Bohemians and Italians in the mining districts of Pennsylvania. Otherwise, scurvy is a rare disease in the United States, except the infantile form.

It was discovered by Captain Cook (1776) that, in order to preserve the health of his crew on long voyages, it was necessary for them to take every opportunity of obtaining *fresh* food. The passage in which Captain Cook describes his experience is worth quoting: "We came to a few places where either the art of man or nature did not afford some sort of refreshment or other, either of the animal or vegetable kind. It was my first care to procure what could be met with of either by every means in my power, and to oblige our people to make use thereof, both by my example and authority; but the benefits arising from such refreshments soon became so obvious that I had little occasion to employ either the one or the other."

*Infantile scurvy* (*Barlow's disease*) occurs in babies, mostly between the sixth and tenth month, and particularly in those not breast fed. Every infant raised on sterilized or proprietary foods for several months, without any fresh or "live" food, is menaced with scurvy. The disease rarely occurs in breast fed babies.

It has been demonstrated that there may be pronounced differences in the value of fresh, unheated milks in their antiscorbutic value, depending on the nature of the diet of the cow or lactating woman.

<sup>27</sup> *Int. Jour. Pub. Health*, Nov., 1920, Vol. I, No. 3, p. 302; also *Scurvy, Past and Present*, J. B. Lippincott Co., 1920.

The antiscorbutic substance is found abundantly in potatoes, fruits, vegetables, green grass and other forage. Cooked foods, with certain exceptions such as tomatoes, are of little value and the milk of a mother whose diet consists largely of cooked or dried or preserved foods may not protect her infant against this disease unless some substance rich in antiscorbutic properties be included. The milk of cows is more effective as an antiscorbutic food when they are fed green foods.

Infantile scurvy is characterized by painful swellings and ecchymoses about the joints, especially the ankles and knees; hyperesthesia; pseudo-paralysis of the lower extremities, due to the pain and hemorrhages; spongy, bleeding gums; hemorrhages from the nose, and occasionally other mucous membranes. In advanced cases, there is also general weakness and marked anemia. Infantile scurvy is often mistaken for rheumatism, infantile paralysis, etc.

When we reflect that it usually requires about six months before a case of scurvy reaches the threshold where it can be recognized clinically, it is clear that during this phase there must be a certain undermining of health. This same condition doubtless occurs in the preclinical period of other deficiency diseases. All babies not breast fed should have orange juice, tomato juice, or some other antiscorbutic.

**Experimental Scurvy.**—The classic experiments of Holst and Froelich<sup>28</sup> in 1912 demonstrated the symptoms and lesions of scurvy in guinea-pigs by means of a diet of cereal grains. These observations have been repeated by Baumann,<sup>29</sup> Jackson, and many others. It is easy to produce or prevent scurvy in guinea-pigs, and to cure it when not too far advanced, simply by the use of antiscorbutic food.

While it seems clear that scurvy is due to the deficiency in the diet of a specific food factor of the vitamin type, other explanations of the disease need consideration. A favorite theory is that the faulty diet undermines health and thus permits infection. Many outbreaks of a disease resembling scurvy during the World War seemed to have an infectious nature. The diagnosis in such cases is not clear, for every weakening disease with a tendency to hemorrhages is not scurvy. The theory that scurvy is an auto-intoxication will not die. Thus, McCollum and Pitz<sup>30</sup> found in the guinea-pigs which had died of scurvy, that the cecum, which is a very large and very delicate pouch through

<sup>28</sup> *Ztschr. f. Hyg. u. Infektionskrankh.*, 1912, 72.

Theobald Smith as early as 1895-96 noted that "When guinea-pigs are fed with cereals (it has been observed for some years in this laboratory), with bran and oats mixed, without any grass, clover or succulent vegetables, such as cabbage, a peculiar disease, chiefly recognizable by subcutaneous extravasation of blood, carries them off in from four to eight weeks." "Bacilli in Swine Disease," Bureau of Animal Industry, 1898-6.

<sup>29</sup> *Am. Journ. Med. Sci.*, 1917, 153, 650.

<sup>30</sup> *Journ. Biol. Chem.*, 1917, 229.

which the food must pass in going from the small to the large intestine, was always packed with putrefying feces. This was soon disproved by Gwens, Hart, Hess, Mendel, Steenbock, Chick, Harden and others who again substantiated the earlier view that the disease is the result of a deficiency of some nutritive factor in the diet.

**Antiscorbutics.**—Certain foods possess the property of preventing scurvy. This is probably due to a special vitamin. The amount of this unknown dietary principle varies greatly in different foods.

The best antiscorbutics are orange and lemon juice,<sup>31</sup> tomato juice, apples, onions, peas, potato, spinach, cabbage, lettuce and the swede. (Table, page 671.) Drying and heating cause a certain amount of deterioration of the antiscorbutic principle in some of these foods. Canned tomatoes, processed at a high temperature, retain their prophylactic properties. Orange juice may be boiled without injury.

Cow's milk at best is only moderately antiscorbutic, and this property is diminished about half by age, by drying, or by pasteurization (page 759). It is destroyed by oxidation.

The prevention of scurvy is plain, and may be summed up in two words—*fresh food*. Arctic explorers, troops, sailors, infants and others on limited diets may avoid scurvy by the use of orange, lemon or tomato juice. The antiscorbutic value of cabbage, lettuce, the swede, onions, potatoes, apples, spinach and fresh raw milk should be resorted to when attainable.

## RICKETS

(*Rhachitis*)

There can be no doubt that rickets is a nutritional disease, but the responsible factors are diet and hygiene. It is characterized especially by an alteration in the growth of the bones. These become enlarged at the extremities and so soft that they bend under the weight of the body. It is a disease of the first two years of life, and is especially prevalent in children in whose diet milk is replaced too largely by cereals and other vegetable foods not suited to the delicate digestive tract of the young child. Predisposing factors in many cases are undoubtedly tuberculosis and syphilis. The symptoms develop gradually. Restlessness and perspiration at night, great sensitiveness of the limbs, so that even a light touch is extremely painful, are characteristic signs of the disease. There are gastro-intestinal disturbances, especially colic and distention of the intestine with gas, so that the abdomen pro-

<sup>31</sup>Alice Hamilton Smith of the Lister Institute has upset the traditional faith in lime juice. It appears that the juice used with good effects in the olden days was in reality obtained from lemons and sweet limes, not from the West Indian sour limes. The sour lime of the West Indies (*Citrus medica-acida*) has only one-quarter the antiscorbutic value of the lemon (*Citrus medica-limonum*). *Lancet*, 2, 725, Nov. 30, 1918.

trudes. The bones become thickened, and nodules develop at the junctures of the ribs with the costal cartilages, forming the characteristic "beaded" ribs. There is defective ossification of the skull; the teeth appear later than normal and in unusual order. Various deformities of the head, spine, chest and limbs result as the child develops. Recovery with deformity is of frequent occurrence.

Rickets is a national public health problem in every country. It is a world scourge preventing the normal development of the young, leaving them damaged not only in their bones, but also in their mental and moral faculties. It is particularly marked among the poor of large cities, who are ill fed and badly housed.

While the only important lesions are found in the bones, it is a very complex pathologic process, the result of disturbed metabolism, which affects nearly all the structures and organs of the body. Rickets is a chronic nutritional disorder.

The cause of rickets is closely related to lack of sunlight and bad hygienic surroundings. Artificially fed children are much more prone to the disease, especially those with faulty feeding. The diet of children who develop rickets is most frequently deficient in fat and often at the same time in protein, while it is apt to contain an excess of carbohydrate. Rickets is due to a lack of Fat-soluble A and to bad hygiene, especially lack of sunlight (ultra-violet rays). Both these factors explain the seasonal prevalence of the disease. Cod-liver oil is a specific preventive and cure.

### PELLAGRA

Pellagra is included among the diseases associated with food, for the evidence indicates that it is caused by a deficient diet of some sort. The disease was long regarded as an example of a food intoxication caused by some toxicogenic saprophyte growing in spoiled corn. Some investigators still look upon pellagra as an infection; and insects (*Simulium* and *Stomoxys*) have been accused of its transmission.

Pellagra usually runs a chronic course, with acute exacerbations, which commonly occur in the spring and at times also in the fall of the year. The disease sometimes runs an acute and rapidly fatal course. The development seems to be more rapid and grave in adults than in children. The "poison," whatever its nature, produces toxic and trophic manifestations. The triad of symptoms are: (1) digestive disturbances, (2) erythema, and (3) nervous disturbances. The final scene usually includes profound cachexia, great muscular weakness, and at times insanity.

Pellagra is a preventable disease in which the social conditions loom large; it is especially prevalent where faulty diet combined with pov-

erty, overcrowding, and misery prevail. It occurs both sporadically and endemically.

The disease was first recognized in America in 1864 by Dr. Gray, of Utica, New York, and by Dr. Tyler, of Somerville, Mass., who each reported a case of probable pellagra. It was overlooked until 1906-1907, when Searcy reported an epidemic in the Alabama Insane Asylum. In the same year (1907) Babcock's article on the cases in the State Insane Asylum of Columbia, South Carolina, aroused our present revival of interest in the disease. In 1908 Wood and Lavinder found four cases in Wilmington, North Carolina. Since then a flood of cases have come to light all over the country, especially in the south; outbreaks, however, occur as far north as Peoria, Illinois, where 258 well-marked cases out of 2,200 inmates were discovered in the State Hospital for the Insane. Lavinder estimated that in 1910 there were between 25,000 and 50,000 pellagrins in the United States. Goldberger estimates that in 1917 fully 125,000 people were attacked with pellagra in the states south of the Potomac and Ohio rivers.

The disease appeared in Italy about 1750, but was first described there in 1771 by Frapolli, of Milan, who applied the name "pellagra" (Italian *pelle*, skin, and *agra*, rough). Marzari in 1810 first called attention to the relation between maize and pellagra. In 1844 Balar-dini first suggested the theory that the disease might be due to spoiled maize, that is, maize which had undergone fermentative change by reason of the growth of fungi on the grain. At present pellagra is most prevalent in northern and central Italy and in Roumania. Triller states that in 1906 there were 30,000 pellagrins in Roumania; in certain parts of Italy as much as 30 to 50 per cent. of the population have the disease; in 1899 there were nearly 73,000 sick with the disease in all Italy, this being upward of 10 per thousand of the rural population. The disease also occurs in Spain, Corfu, Asia Minor, Austria, Servia, Bulgaria, Egypt, and occasionally in India, Africa, the West Indies, Mexico and South America.

As preventive measures must be based entirely upon our conception of the etiology of the disease, it is necessary to consider briefly some of the views upon this subject. Until recently most students of the disease considered pellagra to be an intoxication due to using Indian corn (maize) as a food, which, under the influence of some parasitic growth (bacteria or fungus), has undergone certain changes with a production of one or more toxic substances. Lombroso, who studied this subject for years, made alcoholic and watery extracts from spoiled maize and obtained chemical substances of an undetermined nature, which were given to men and animals with the production of symptoms analogous to pellagra. This work has not been confirmed and furthermore Lombroso's interpretation is doubtful.

With regard to the parasites found on maize, it may be said that the varieties are numerous, and no single one seems to be constant enough to be rated as the definite causative agent. Ceni incriminated the *Aspergillus fumigatus* as the cause of the maniacal form of pellagra, and the *Aspergillus flavus* as the cause of the depressive form. These molds have resisting spores which withstand heat, hence ordinary cooking is not sufficient to destroy them. The *Bacterium maydis* has also been associated with the disease. Lombroso, as a result of his studies, maintained that pellagra is due to a poison (toxin) developed in maize by saprophytic microorganisms (molds or bacteria), in themselves harmless to man.

Other views concerning the nature of pellagra are: that it is an auto-intoxication, the poisonous substances being produced in the bowels as a result of the constant and almost exclusive diet of corn, which produces certain changes in the intestinal flora, and the production of poisonous substances. A somewhat similar view is that the disease is an intestinal mycosis, the offending microorganisms being eaten with corn and colonizing in the intestinal tract. Others regard the disease as of an infectious nature, and several parasites have been reported in the blood and organs. In France especially the idea has been brought forward that pellagra is not a definite morbid entity at all, but a symptom-complex sometimes observed in alcoholics and cachectic states of diverse origin, the erythema being regarded only as a common solar erythema. Sambon, as the result of epidemiological studies, brought forward (1905 and again recently) the view that pellagra is an insect-borne disease, and incriminates the *Simulium reptans*.

Raubitschek <sup>32</sup> recently brings forward evidence that pellagra depends upon some noxious substance (*nox*) activated by the action of sunlight. This is the photodynamic theory, and corresponds to the action of light upon a photographic negative. It is suggestive that the skin lesions in pellagra are mainly confined to the exposed surfaces. There is also a substance in buckwheat poisoning (*fagopyrismus*) that affects animals exposed to the light, but not those kept in the dark.

The Thompson-McFadden Pellagra Commission, consisting of Siler, Garrison and MacNeal, believe that pellagra is a communicable infection and is in some way associated with unsanitary methods of sewage disposal. They found that the immediate results of hygienic and dietetic treatment in adults have been good, but after returning to former conditions of environment most of the cases have recurred.

Goldberger <sup>33</sup> on the other hand regards pellagra as a disease due to a dietetic fault. Goldberger insists that pellagra is not a communicable

<sup>32</sup> *Berliner klin. Wochens.*, Vol. XXIII, No. 26, June, 1910.

<sup>33</sup> *Journal American Medical Association*, February 12, 1916, LXVI, p. 471; also, *P. H. Reports*, October 23, 1914; November 12, 1915; October 22, 1915; March 19, 1920.

disease, but is essentially of dietary origin; that it is dependent on some yet undetermined fault in diet, which fault may be corrected by the addition, in sufficient amount, of fresh animal protein foods, especially milk. Pellagra never develops in those consuming a mixed, well-balanced and varied diet.

Among the people in those districts where there is a high incidence of pellagra in the spring and summer months, it has been shown that their winter diets are composed largely of seeds and seed products and that the amounts of leafy vegetables, milk, eggs and meat, are very small, or are entirely absent, for varying periods.

Goldberger produced pellagra in six out of eleven volunteer convicts in a camp at Jackson, Mississippi, as a result of a one-sided diet, consisting mainly of carbohydrates (cereals). The first typical dermatitis appeared five months after the beginning of the restricted diet. Other manifestations included nervous and gastric symptoms. None of the controls became pellagrous. Still more striking is the evidence obtained by Goldberger in preventing the recurrence of pellagra in orphan asylums and in groups of insane pellagrins in an institution in the south by introducing a varied and better balanced diet, all other conditions remaining the same. Furthermore, a number of clinicians report that pellagra, if not too far advanced, may be cured upon the assumption that it is produced through dietary faults. It is scarcely necessary to look further for the cause of a disease that may be produced by a restricted diet, prevented and cured by a proper diet. I believe Goldberger has proved his case and that his work stands as one of the achievements in preventive medicine.

Pellagra, beriberi and scurvy are evidently closely allied diseases.

**Corn.**—In Europe pellagra was long associated with the consumption of spoiled maize as the chief article of diet, but it is now known that the eating of this grain has nothing whatever to do with its causation. The fact remains that it constitutes a large portion of the faulty dietary of many persons who develop the disease. A consideration of this important grain is here given on account of its public-health importance.

Maize or Indian corn is a native of the Western Hemisphere and was cultivated by most of the northern and western tribes of North American Indians before Columbus reached these shores. The importance of the corn crop today may be gathered from the fact that, according to the census of 1900, almost one-third of all the land under cultivation in the United States was devoted to corn. It was grown on 88.6 per cent. of all the farms in the country in the crop for 1889. The value of the annual crop now exceeds a billion dollars. Corn contains 24.7 per cent. of water. The water-free material consists of 12.7 per cent. proteins, 4.3 per cent. fat, 79.3 per cent. starch, sugar, etc., 2 per cent. crude fiber, and 1.7 per cent. of mineral matters. The several nutrient substances

in corn and other common cereals are much the same; the individual compounds, however, making up these groups, differ considerably.

The kernel (see Fig. 74) or seed, it must be remembered, is not inert, but a living thing which, under favorable conditions, will develop into a new plant, and each part of it is made up of cells especially fitted for a particular rôle in this process of reproduction. Roughly speaking, a seed consists of three divisions: the skin, the germ, and the endosperm. It is a well-known fact that corn, when allowed to ripen before it is taken from the stalk, keeps much better than immature corn. It is certain that protective substances (antibodies) are developed in the kernel which retard the growth of bacteria and molds. Moist corn kept warm spoils readily, whereas corn once thoroughly dried is proof against serious fermentative changes.

The prevalence of pellagra in our Southern States has been attributed to the fact that during the past decade or two the corn belt has gradually been pushed farther and farther north. This means that it is often harvested before it is mature, and the chances of its spoiling are favored in transporting it to our southland in a moist condition. A carload of corn starting from the Great Lakes may ferment and become so overheated on its journey south that occasionally it catches fire spontaneously. These facts have been given to account for the supposed increase in pellagra in our southern cities.

The tests for spoiled corn are not entirely satisfactory. They may be divided into physical, biological, and chemical tests. The physical test consists mainly in the luster, the absence of molds, the odor, and the taste. The biological test consists in planting the corn; from 90 to 95 per cent. should germinate. The chemical test includes among other determinations the proportion of ash after burning, and Gosio's phenolic reaction with ferric chlorid. A green purple color with this reagent indicates fermentation, with the production of phenolic compounds.

Spoiled corn may be renovated by polishing and then heating, to prevent further growth of molds. It is difficult to detect renovated corn by inspection alone, but the biological test will disclose whether or not it has been heated. The practice of renovating corn should either be prohibited or be placed under strict official control.

**Prevention of Pellagra.**—The line along which pellagra prophylaxis is planned depends entirely upon our conception of the disease. As pellagra prevails especially among the poor, but particularly the ignorant with defective dietaries, it at once becomes evident that economic and social improvements are an important part of the program. Prophylaxis spells prosperity in this disease as in others. In a study of cotton mill villages during 1916, Goldberger<sup>34</sup> found that, in general, pellagra incidence varied inversely according to family income.

<sup>34</sup> *Public Health Reports*, Nov. 12, 1920, XXXV, 46, p. 2673.

In accordance with Goldberger's views pellagra may be prevented and even eradicated by substituting a mixed, well-balanced, varied diet for the restricted, one-sided diet so common in pellagrous communities. Emphasis should be laid upon a larger proportion of the fresh animal protein foods, such as milk, lean meat, eggs, and green vegetables, such as snap beans, turnip greens, spinach and the like.

Goldberger suggests the following as a sample of a minimum pellagra-preventing bill of fare arranged to suit the dietary habits of the people among whom the disease is most prevalent in the South:

## PELLAGRA-PREVENTING BILL OF FARE

### BREAKFAST

Sweet milk, daily.

Boiled oatmeal with butter or with milk every other day.

Boiled hominy grits or mush with a meat gravy or with milk every other day.

Light bread or biscuit (one-fourth soy-bean meal), with butter, daily.

### DINNER

A meat dish (beefstew, hash, or pot roast, ham or shoulder of pork, boiled or roast fowl, boiled or fried fish, or creamed salmon or codfish cakes, etc.), at least every other day.

Macaroni with cheese, once a week.

Dried beans (boiled cowpeas with or without a little meat, baked or boiled soya beans with or without a little meat), two or three times a week.

Potatoes (Irish or sweet), four or five times a week.

Rice, two or three times a week, on days with the meat stew or the beans.

Green vegetables (cabbage, collards, turnip greens, spinach, snap beans or okra), three or four times a week.

Corn bread (one-fifth soy-bean meal), daily.

Buttermilk, daily.

### SUPPER

Light bread or biscuit (one-fourth soy-bean meal), daily.

Butter, daily.

Milk (sweet or buttermilk), daily.

Stewed fruit (apples, peaches, prunes, apricots), three or four times a week, on days when there is no green vegetable for dinner.

Peanut butter, once or twice a week.

Sirup, once or twice a week.

The Italian struggle culminated in the law of 1902 for "the prevention and cure of pellagra," which was inspired by Lombroso's views.

The Italian measures may be summarized as follows: those aimed at the cure of the disease are a free distribution of salt (a government monopoly in Italy), the distribution of food either at the homes of the patients or through sanitary stations, and the treatment of severe cases in hospitals for pellagrins and in insane asylums. The prophylactic measures are mainly directed against the use of spoiled corn as an article of food. They comprise a census of the disease and a report of all cases; the exchange of good corn for spoiled corn; desiccating plants; cheap coöperative kitchens; the improvement of agriculture; and the education of the people. The corn is inspected by experts and is submitted to certain tests. If found spoiled, its sale for food is prohibited.

The supposition that the ingestion of good or spoiled maize is an essential cause of pellagra is not supported by the studies of the Thompson-McFadden Pellagra Commission.<sup>35</sup> They believe that pellagra is, in all probability, a specific infectious disease communicable from person to person by means at present unknown. The Commission discovered no evidence incriminating flies of the genus *Simulium*, and state that if pellagra is distributed by a blood-sucking insect, *Stomoxys calcitrans* would appear to be the most probable carrier. The Commission is inclined to regard intimate association in the household, and the contamination of food with the excretions of pellagrins as possible modes of distribution of the disease. They claim to have eradicated pellagra from a milk village in South Carolina by substituting a water carriage sewerage system for surface privies.

In my opinion, Goldberger's views of pellagra are correct. The disease may be prevented, produced, and even cured, if not too far advanced, in accordance with the view that it is caused by a faulty dietary. Before pellagra is eradicated, it will mean general education concerning balanced diets and general prosperity sufficient to purchase the necessary articles making up such a diet.

## FOOD POISONING <sup>36</sup>

**General Considerations.**—There are two well recognized causes of food poisoning. (1) *Food infection*, caused by *Bacillus enteritidis*, or closely allied microörganisms. Bacteria other than the Gaertner group

<sup>35</sup> Siler, J. F., Garrison, P. E., and MacNeal, W. J.: "Pellagra. A Summary of the First Progress Report of the Thompson-McFadden Pellagra Commission." *J. A. M. A.*, Jan. 3, 1914, LXII, 1, p. 8.

<sup>36</sup> Food "poisoning" is not a good term, for almost all cases are infections or intoxications. The phrase "food poisoning" includes all instances of acute food injury and is accepted because it has become current in the literature.

of bacilli are suspected of causing food poisoning, but the relationship has not been established.

The first important landmark in the bacteriological investigation of food poisoning was the isolation by Gaertner in 1888 of *Bacillus enteritidis* from an outbreak at Frankenhausen. The bacillus was isolated both from the fatal case and from the organs of the cow, killed on account of enteritis, the consumption of whose meat caused the outbreak. (2) *Food Intoxication* due to toxins preformed in the food. Botulism is the only known example in this class. Other bacteria may produce toxins in food, but none of these have been demonstrated to be poisonous by the mouth.

There is a great clinical difference between these two classes of food poisoning. Food infection is an acute disease characterized by nausea, vomiting, cramps and diarrhea, and fever. Botulism is characterized by nervous symptoms, paralysis, constipation and no fever. The symptoms vary greatly in severity. The mortality of food infections is rarely over 1 per cent.; botulism is fatal in from 50 to 100 per cent. of those attacked.

The period of incubation is usually 8 to 28 hours, often longer. Frequently several meals intervene between the time the infected food is eaten and the onset of the disease. Vomiting is often the first symptom and suspicion at once points to the food vomited, whereas it may have been due to something eaten a day or two before. This mistake is common.

Various classifications of food poisoning have been attempted; none are satisfactory except those based on etiology. The commonest mistake is to classify food poisoning according to the food responsible, as meat poisoning, cheese poisoning, potato poisoning, milk poisoning, etc., etc. As a matter of fact, food infection is the same disease, whether the bacteria are conveyed in meat, milk, potatoes, or salad. Botulism is the same whether it comes from sausage, brawn, beans, peas or olives.

Most instances of food poisoning are from food that is prepared or preserved in some way. There is little danger in fresh food. The chief offenders are chopped meat, sausage, meat pies, salads, brawn, and other food that is pickled or preserved. Food that is prepared hours before it is eaten gives opportunity for the growth of bacteria, especially in the summertime.

The health of food handlers is an important factor. This applies especially to those who handle milk and milk products. Meat and other foods may be infected from cases or carriers of disease. Harris and Dublin<sup>37</sup> examined 1,748 food handlers and found 10 cases of active tuberculosis and 41 with evidence of syphilis, of which 37 occurred among waiters.

<sup>37</sup> Mono. Series, No. 17, N. Y. C. Dept. of Health.

There is a common opinion that food poisoning is exceedingly frequent. This is a mistake, certainly in this country. No satisfactory figures are available. Outbreaks apparently occur much more frequently on the Continent of Europe than in England, and more frequently in England than in the United States. Savage tabulates only 112 British outbreaks of bacterial origin, apart from botulism, studied from 1878 to 1918.

Mayer presents a list of 48 food poisoning outbreaks which occurred in Germany between 1888 and 1911, and which were attributed to *B. enteritidis*. Bainbridge states that in Germany between 1898 and 1908 there were at least 261 outbreaks due either to *B. suipestifer* or *B. enteritidis*.

Ostertag, in 1902, was able to collect records of but 85 epidemics in the period 1880-1900, mostly of German sources. Very few outbreaks appear in the literature from the United States. If the affection were made reportable, it would facilitate the study of the problem.

The number of persons involved in outbreaks varies from one to several hundred. The larger outbreaks are almost all caused by infected milk. Thus, at Newcastle-on-Tyne, in October and November, 1913, 523 persons were affected by milk containing *B. enteritidis*, and a similar outbreak occurred in the same place in 1914, affecting 468 persons from the same cause. Usually the number of individuals affected is limited to one or two families, or to the participants of a meal or banquet.

Acute attacks with gastro-enteric symptoms are not necessarily due to harmful foods. This is a common mistake in diagnosis. Nausea, vomiting, cramps or diarrhea may be due to indigestion, indiscretions in diet, eating when fatigued; also to exposure. The gastro-intestinal tract is exceedingly sensitive to reflex nervous influences; thus, emotion may cause vomiting or diarrhea. Nervous exhaustion is a frequent cause of gastro-enteric disturbance. Organic diseases of the heart or kidneys are often associated with gastric symptoms. Nausea and vomiting often usher in acute infectious diseases, especially in children. In addition to the above, we have found in our studies at Harvard that "ptomain poisoning" has been mistaken for cerebrospinal fever, malignant tumor, anaphylaxis, dysentery, etc.

Food infection has a summer prevalence, similar to other intestinal diseases, such as typhoid fever, cholera, and dysentery. Botulism shows no particular relation to season.

No reliance can be placed upon the taste, odor or appearance of food. On the other hand, food showing evidence of abnormal fermentation or any putrefaction should not be eaten.

*B. enteritidis* and allied intestinal bacilli cannot be detected by our unaided senses. The toxin of botulism is usually associated with spoiled

food, but the evidence of spoilage may not be sufficient to attract attention.

The general principles of prevention consist in having our food as fresh and clean as possible; when processed the methods must be satisfactory. If preserved by heat, the temperature and time of processing must be sufficient to render the food sterile. If refrigerated, the temperature must be at or near the freezing point. If pickled, the brine must be sufficiently strong to prevent bacterial growth.

Finally, our ultimate safeguard rests with cooking. Both *B. enteritidis* and the toxin of botulism are comparatively thermolabile. The cooking, however, must be thorough in order that the heat may penetrate throughout the mass. Food may be contaminated after cooking—even sterile canned goods may be infected after the contents of the can are exposed. The bacilli belonging to the Gaertner group are non-spore bearing bacteria and are readily killed in a few minutes at 70° C. This temperature, however, is frequently not reached in the center of a joint of meat, a dish of vegetables, or a pie. Küchenmeister found that joints require boiling for several hours for the interior to reach a temperature of 77° to 80° C. Meat is a poor conductor of heat. Perroncito placed a ham of about 6 kilos weight in cold water which was then raised to the boiling point. The water boiled when the interior of the ham was only 25° C. After 35 minutes, it was 35-40° C., and after 2 hours, the temperatures in different parts of the interior were 46°, 55°, 58°, 62°, 64°, and 67° C. Rupprecht found that boiling for 45 minutes as practiced in Saxony did not produce a higher temperature than 75° C., and this only in thin pieces of meat. He found that the interior temperature of a rapidly roasted sausage was only 28.7° C.

Delepine and Howarth carried out experiments upon the temperatures reached in baking meat pies. They noted that the temperature of the center of the pie, said to be underbaked, but having all the external appearances of being well baked, did not exceed 47.2° C. The center of a pie obviously overbaked and acknowledged to be so, had not reached beyond 86.6° C. Delepine points out that pies might be so cooked that bacteria might continue to grow in their center during the greater part of their stay in the oven, and the bacteria would certainly not be killed. Sawyer found that typhoid bacilli survived in a dish of spaghetti cooked until the surface was dark brown (page 115).

Special methods of prevention are discussed in detail under each form of food poisoning.

## FOOD INFECTIONS

Food infection is almost always associated with Gaertner's bacillus (*B. enteritidis*), or a closely allied species. This form of food infection is also called food poisoning, and commonly miscalled "ptomain poisoning." Since meat is the chief vehicle for this infection, it is often called "meat poisoning," but milk, cheese and other milk products, as well as vegetables, may become infected and be the vehicles of these pathogenic bacilli.

**Incubation Period.**—Usually from 6 to 12 hours elapse between the ingestion of the food and the onset of symptoms. Occasionally the period of incubation is 4 hours or less, and may be 72 hours or more. Not only does the incubation period vary in different outbreaks, but in the same outbreak widely different incubation periods have been noted.

**Symptoms.**—The symptoms are essentially those of an acute gastrointestinal irritation, namely, nausea, vomiting, abdominal pain and diarrhea. The onset is usually sudden. The attack may be ushered in with headache and a chill. The abdominal pain is frequently the first symptom and may be gripping and severe. The diarrhea usually consists of repeated bowel actions, which as a rule are offensive. Later in the attack, the stools become more watery and frequently of a green color. Faintness, muscular weakness and prostration may be quite marked. Thirst is always present. There is almost always a rise of temperature, usually to about 102°-103° F. Various nervous manifestations, such as restlessness, muscular twitchings, and drowsiness may occur, but these symptoms are not constant or marked. Oliguria is often present. Herpes and other skin rashes have been noted.

The severity of the symptoms varies greatly in different outbreaks, and even in the same outbreak. All degrees are met with, from fulminating cases, fatal within 24 hours, to those of slight diarrhea and malaise, insufficient to keep the patient from work. Usually the attack is over in a day or two, with prompt recovery; although occasionally marked prostration may persist. The severity doubtless depends upon the virulence of the particular strain of bacilli concerned, the length of time it had to grow upon the incriminated food before consumption, and the temperature of growth. The symptoms vary with the dose, also with the susceptibility of the individual which plays an important rôle in this as in other infections.

The case *fatality* rate varies greatly in different outbreaks. In the 112 British outbreaks studied by Savage, there were some 6,190 cases with 94 deaths, a case fatality rate of 1.5 per cent.

The age and sex *distribution* depends entirely upon the accidental age and sex distribution of those who eat the infected food.

Most cases occur in the summer time, corresponding to the seasonal prevalence of typhoid fever, cholera, dysentery and other intestinal infections. The bacilli responsible for food infection grow in the food before it is eaten, and therefore temperature is a very important factor. The greater multiplication of these bacteria in hot weather also increases the opportunities for transmission of infection through flies and other means. Secondary infections rarely occur. There is the same potential possibility of contact infection as in typhoid fever, but the cases of food infection are for the most part acute and of short duration, so that there is little opportunity for secondary infection.

An outbreak investigated by Savage in 1908 serves as an illustration:

"On Friday, May 8, 1908, in Murrow, a village in Cambridge-shire, a woman purchased some pork bones from a local butcher and that evening used them to make some brawn. The following morning the brawn was emptied out of the saucepan in which it had been made and, without cleansing the vessel, potatoes and asparagus were cooked in it. These vegetables were eaten for midday dinner by four persons and all were subsequently attacked with vomiting, diarrhea, and the other symptoms of food poisoning, two in the night and two the next morning. The husband, who was away at midday, remained well and unaffected.

"On Monday, two days later, the brawn made up into pork cheeses (a local name for brawn) was given away to three different neighbors and was consumed by a further fourteen persons, all of whom were attacked with similar symptoms after an incubation period varying from twelve to forty-eight hours. Three of the eighteen attacked died. No one eating the brawn escaped.

"None of the brawn was available for examination, but from the only fatal case investigated a Gaertner group bacillus (*B. aertrycke*) was isolated and its connection with the outbreak was further proved by the fact that it was agglutinated in high dilution by the serum of three survivors.

"The brawn was home prepared, and the materials were slowly heated for several hours with a short boil at the finish, but obviously actual boiling temperature was not reached. That the Gaertner bacilli were present before preparation and survived cooking is evident from the infection imparted to the vegetables through the uncleansed saucepan. Further inquiries elicited that the pig which supplied the bones for the brawn had suffered from local injury or disease of one leg, no doubt due to infection by this food poisoning bacillus.

"Here are all the commonly present features of such outbreaks. A typical group of symptoms, a number of cases geographically sep-

arated but linked by a particular food consumed in common, a special bacillus demonstrated to be the pathological cause, and lastly (unlike most outbreaks) with definite evidence connecting it with disease in the animal supplying the incriminated food."

**Taste, Odor and Appearance.**—It cannot be too strongly emphasized that in the vast majority of outbreaks of food infection the food affected is not noticeably altered in either appearance, taste or smell. The prevalent idea that poisonous food must be "tainted" still persists, although long exploded. Bacilli belonging to the Gaertner bacillus group cannot be detected in food or water, any more than typhoid bacilli, dysentery bacilli or cholera vibrio can be detected with our unaided senses.

In the Ghent outbreak, investigated by van Ermengen in 1895, a slaughterhouse inspector (a veterinary surgeon) was so certain that the suspected meat (saveloy), in the absence of any abnormal signs, could have no connection with the trouble, that he ate two or three pieces of it to demonstrate its harmlessness. He was attacked with severe cholera-like symptoms, and died five days later, the Gaertner bacillus being recovered postmortem.

In a few of the outbreaks, however, minor peculiarities of the food have been noted, such as objectionable flavor, heavy odor, moist or soft condition, etc. These, however, are rare exceptions and not the rule.

**Kind of Food Responsible.**—The great majority of outbreaks are due to meat foods, and hence this form of food infection is often called meat poisoning. Of the 112 British outbreaks, in 21 the vehicle was a non-flesh food; that is, milk, 1; cream, 1; ice cream, 6; potatoes, 2; pineapple jelly, 1; canned peaches, 1; rice cooked in fat, 1. The remaining ninety were all due to flesh food, mainly brawn, meat pies, pork, ham, beef, etc. The meat of the pig or ox accounts for 68 per cent. of the British and 61 per cent. of the Continental outbreaks. The almost complete absence of outbreaks due to the meat of the sheep is striking. The number of cases ascribed to fish is small.

Most outbreaks are due to some form of prepared meat foods, such as brawn, meat pies, sausage, chopped meat, etc. When the nature of the infection is considered, the more the food is handled and the longer it lies around, the greater the opportunity for it to become contaminated and for the bacteria to grow and multiply.

**Diagnosis.**—Diagnosis of food infection depends upon: history of exposure to the suspected food; symptoms suggestive of food poisoning; isolation of the infecting organisms from the suspected food, and also from the blood, urine, feces, or viscera of the patient (bacilli belonging to the Gaertner group disappear from the feces in from 7 to 10

days after the onset of symptoms), specific identification of the causative organism by agglutination tests; demonstration of agglutinin in the blood serum of patients. A positive reaction can be detected 6 or 8 days after the onset of symptoms. Agglutination in comparatively low dilutions is usually accepted as diagnostic owing to the fact that it is extremely rare to find a positive reaction for *B. enteritidis* or *B. suispestifer* in normal individuals.

For a better understanding of food infection and its prevention, it is necessary to know the habitat, cultural and biological properties, as well as the toxin production, of the Gaertner group of bacilli responsible for this disease. The Gaertner group is a subdivision of the colon-typhoid group.

#### THE COLON-TYPHOID GROUP

The colon-typhoid group is a large class of important organisms which has the typhoid bacillus at one end and the colon bacillus at the other. The intermediate forms in this group comprise the paratyphoid bacilli, the dysentery bacilli, the hog cholera bacilli, the *Bacillus psittacosis* (a disease of parrots communicable to man), the *Bacillus icteroides* (once associated with yellow fever), the *Bacillus typhi murium* (the bacillus of mouse typhoid, the type of the bacterial rat viruses), the *Bacillus enteritidis* of Gaertner (associated with food infection and diarrheal diseases), and many others.

The organisms comprising this group are so closely related that it is often difficult to determine where specific differences begin and terminate. This group may be taken as a beautiful instance of missing links, and a study of these closely related organisms excites the imagination to the belief that we may here see evolution in the making (see table, page 700).

The differentiation of the typhoid-colon group based upon fermentation tests is shown in the following statement from Savage.<sup>38</sup>

#### THE GAERTNER GROUP

The *Gaertner group*, of which *B. enteritidis* is the type, occupies an intermediate position between the colon bacillus on the one hand, and the typhoid bacillus on the other. It is also called the "*intermediate group*," the "*hog cholera group*," the "*enteritidis group*," the "*paratyphoid group*," and the "*Salmonella group*."

The classification of the members of this group is quite involved, and there is still a lack of agreement among different investigators concerning some of the details. The important members are as follows:

*B. Enteritidis*.—Gaertner, in 1888, brought forth the first definite

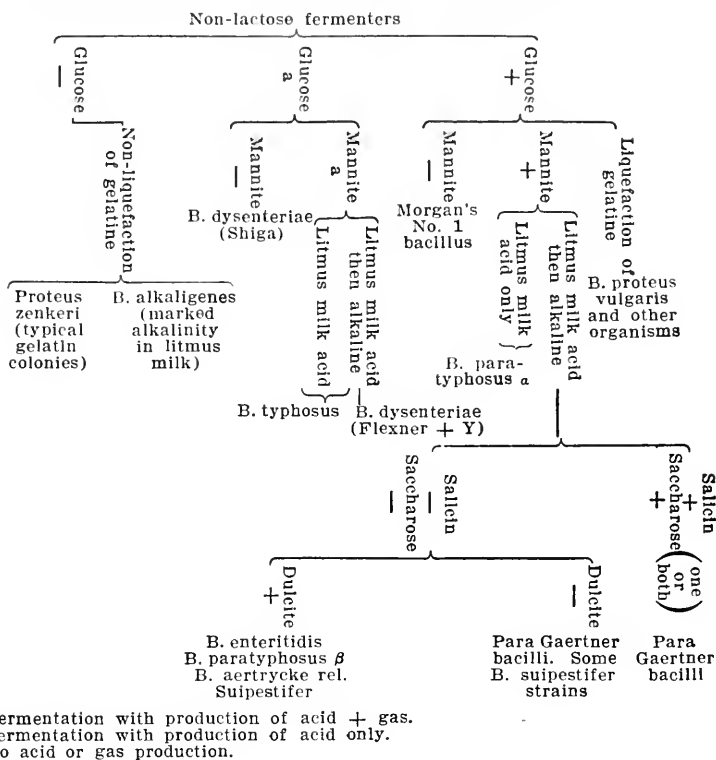

<sup>38</sup> "Food Poisoning and Food Infection," page 238.

All the members of this group are gram negative bacilli. They all have their normal habitat in the intestinal tract. As a rule, those that are most active in fermenting sugars are the least pathogenic, and vice versa.

## DIFFERENTIATION OF THE TYPHOID-COLON GROUP

evidence which incriminated bacteria as an etiologic factor in food poisoning. At Frankenhausen, 57 individuals became ill after eating the flesh of a cow which had been slaughtered on account of enteritis; one case resulted fatally. Gaertner isolated the bacillus from the organs of the cow and also from the spleen of the man who died. He called the organism *B. enteritidis*. It has since been shown to be the common etiologic factor in food poisoning. It is the type of the group.

*B. mortificans boris* was isolated by Basenau in 1893 from the muscles and viscera of a cow killed on account of puerperal metritis. There is little doubt but that this organism is identical with *B. enteritidis* of Gaertner.

*B. suipestifer*, also called *B. cholera suis*, or the hog cholera bacillus, was isolated by Salmon and Theobald Smith in 1885. For a long time this was believed to be the cause of hog cholera, but it is now known to be a secondary invader. It is often used as a group type. Man is not susceptible to hog cholera, which is due to a filtrable virus. There are doubtless many strains of the hog cholera bacillus, only some of which are pathogenic for man, for no relationship has been found between hog cholera and food poisoning in man; in fact, pork has been eaten

many times from hogs with hog cholera without ill effect. This is an illustration of the difficulties and confusion in this group of bacilli.

*B. aertrycke* was isolated in 1898 in Hatton, England, and by De Nobele in Aertrycke, Belgium. This organism is known to be identical with *B. suipestifer*.

*B. psittacosis* was isolated by Nocard in 1893 from the bone marrow of parrots which had died en route from Buenos Aires to Paris. It is also associated with a highly fatal, pneumonia-like disease in man in Paris. Bainbridge regards *B. psittacosis* as identical with *B. suipestifer*. The organism is now only of historical interest, because there has been no recurrence.

*B. typhi murium* was isolated by Loeffler in 1893 from an epizootic among his laboratory mice. This organism is closely related to *B. suipestifer*. Bainbridge pointed out that the name was applied to either pure cultures of *B. enteritidis*, or to mixed cultures of *B. enteritidis*, *B. suipestifer*, and *B. paratyphosus*  $\beta$ . Shibayama reported instances of human illness resulting from infection with the cultures of *B. Typhi murium* used as a rat virus.

*Danysz's virus* consists of a culture of a bacillus isolated from an epizootic among harvest mice. Bainbridge has shown that it is identical with *B. enteritidis*.

*B. icteroides* was isolated by Sanarelli in 1898 from yellow fever patients, and believed by him to be the cause of the disease. Reed and Carroll, in 1899, showed that it was culturally identical with *B. suipestifer*, and it has now only historical interest.

*B. paratyphosus*  $\beta$  was isolated by Acharde and Bensande in 1896, but carefully studied by Schottmüller in 1900. Brion and Kayser, in 1902, named the two types *B. paratyphosus*  $\alpha$  and *B. paratyphosus*  $\beta$ .

In England, the term *B. paratyphosus*  $\beta$  is limited to those strains which are identical, by culture, agglutination and absorption tests, with the original strain of Schottmüller. Such a restriction is not yet generally accepted, however, and consequently considerable confusion has arisen. See also paratyphoid fever, page 136.

The English, due chiefly to the careful observations and absorption tests of Bainbridge, Bainbridge and O'Brien, and the studies of Savage, believe that only three organisms are involved in cases of food infection: namely, *B. paratyphosus*  $\beta$ , *B. suipestifer* and *B. enteritidis*. The Germans, however, regard *B. paratyphosus*  $\beta$  and *B. suipestifer* as one and the same organism. If the strain comes from an animal they call it *B. suipestifer*; if from man, *B. paratyphosus*  $\beta$ .

It is evident to the student of bacteriology that the confusion in this and other groups is due first of all to the fact that we have no clear-cut criteria of genera, species and strains among bacteria; second, to the fact that we are dealing with biologic variables. Thus, a strain

may be cultivated so that certain cultural and biologic properties are entirely changed. These differences are probably always variants, rarely if ever of the magnitude of mutants. It is true that sometimes the changes thus produced seem fixed in that they breed true to type, but usually they revert when placed under proper conditions.

We do not know the significance of the differences between *B. enteritidis*, *B. cholerae* *suis* and *B. paratyphosus*  $\beta$ .

**Toxin Production.**—The organisms of the Gaertner group are said to produce soluble toxic substances which are heat resistant. This, however, is almost entirely theoretical. Cathcart, for example, as well as a number of other workers, such as Brion and Kayser, Kutcher and Meinicke, Levy and Fornet, found no evidence of soluble toxins, while others, such as Uhlenhuth, Zwick and Weichel, and Vaughan found evidence of toxic bodies in the filtrates. A review of the literature on this subject up to 1917 is given by Ecker who found that soluble toxic substances are produced within 24 hours by some strains of *B. paratyphosus*  $\beta$ .

Aronovitch, working in my laboratory, found that filtrates of broth cultures of some strains of the Gaertner group are toxic when injected into mice or guinea-pigs. The filtrates of young (24-hour old) cultures are destroyed at 75° C., but when 7 days old, are destroyed only at 100° C. in from one to two hours. There is no evidence whatever that these substances are poisonous or even irritating when taken by the mouth. The symptoms produced when these filtrates are injected into animals have no resemblance to food poisoning. The nature of the poisonous substances in these filtrates is problematical, and the relation to true toxins has not yet been established.

Most writers on the subject of food poisoning state that when the period of incubation is short it is due to the ingestion of toxins produced in the food before it is eaten. This is entirely conjectural. Endotoxins have also been invented to account for the facts. How microorganisms, such as the Gaertner bacilli group, injure the tissues of the host is part of the problem of the pathogenesis of infectious processes, which is still far from solution.

#### SOURCES OF INFECTION WITH THE GAERTNER GROUP

**Diseased Animals—Antemortem Infection.**—*B. enteritidis* and its congeners are pathogenic for some of our food animals, as well as for man. Cattle suffering during life from puerperal fever, uterine inflammations, navel infection (in calves), septicemia, septic pyemia, diarrhea, and local suppurations are apt to furnish meat containing the Gaertner bacillus or closely related bacilli. Such meat has frequently given rise to meat poisoning. Hence, emergency slaughter (Nothschlacht) unless

intelligently supervised, furnishes meat that may be a menace. The meat of such animals presents no warning signs of its danger. This fact was well proved by the meat inspector at Ghent who lost his life because he was so sure that meat must be tainted to be harmful. The story of this tragedy has become classic (page 698).

**Postmortem Infection.**—The meat may come from healthy animals, but become infected after slaughter. This may take place through the hands or instruments of the butcher who has just handled a diseased carcass. There are other possibilities, such as human carriers, fecal contaminations, etc.

**Human Carriers.**—Bainbridge states that "infection of meat by human carriers of *B. suipestifer* is unknown." Human carriers of *B. enteritidis* are exceedingly rare. Human carriers of *B. paratyphosus*  $\beta$  are occasionally discovered, but these also are infrequent. In 4,154 specimens of human feces from healthy individuals examined in my laboratory in 1917-18, not a single carrier of any of these non-lactose fermenters was found.

The English observers believe that all cases of food poisoning traced to human carriers are in reality cases of paratyphoid fever, but the Germans, who do not differentiate between *B. paratyphosus*  $\beta$  and *B. suipestifer*, hold that the latter organism also occurs in normal, healthy human intestines, and may thus become a source of food infection. Such instances must be exceedingly rare in the United States, for in our studies of the subject we have not found a single instance in three years.

**Rats and Mice.**—The common gray rat and mice may harbor *B. suipestifer* and possibly *B. enteritidis* as carriers. Zwick and Weichel examined 177 mice and found that 28 were acting as carriers of Gaertner group bacilli. Hence, food may become infected by contamination with rat or mice feces. There is abundant opportunity for such contact in the slaughterhouse, in butcher shops, in refrigerator plants, in transportation, and in the home.

**Rat Viruses.**—Food has occasionally become contaminated by contact with bacterial viruses used against rats. These viruses are pure cultures of *B. typhi murium*, closely allied to *B. enteritidis*. Shibayama reported instances of human illness resulting from the free use of such cultures.

**Contamination with Fecal Bacteria.**—This source of infection is highly improbable, for if it were true, food poisoning would be exceedingly common, so great is the ordinary fecal contamination of our food. During the years 1917-18, over 500 samples of food were examined in my laboratory without finding a single pathogenic member of the colonyphoid group.

**Food Poisoning of Non-Specific Bacterial Origin.**—A number of other bacteria have been associated with food poisoning, such as *B. proteus*, *B. fecalis alkaligenes*, *B. prodigiosus*, and even the colon bacillus itself. There is slight evidence that any of these are ever responsible for the trouble in question.

Another view is that massive infection of food with fecal and other bacteria may cause symptoms of gastro-intestinal irritation. That this is unlikely, or at least unusual, is evidenced by the enormous numbers of bacteria, including fecal bacteria, taken with milk, cream, butter and other milk products; also in cheese, sauerkraut, sausage, etc., etc. Food very massively infected with *B. coli* and other intestinal bacteria and given to animals to eat does not cause infection or illness.

All the evidence points to the cause of food infection as due to specific organisms belonging to the Gaertner group.

The **prevention** of food infection starts with the meat inspector. Animals suffering with any septic or pyemic lesions, whether local or generalized, should be condemned as unfit for food purposes, unless bacteriologic examination excludes the Gaertner group bacilli. These infections may be discovered either antemortem or postmortem. Food animals suffering with puerperal sepsis or enteritis are especially suspicious. The greatest care should be taken with sick animals killed under the provisions of emergency slaughter (Nothschlacht).

Pains must be taken to disinfect hands, tools and surfaces in case such an animal comes to the slaughterhouse, to avoid the infection of other carcasses. Cleanliness must be exercised in butchering, handling, storing and transporting meat. Every care must be exercised to guard it against contamination with rat and mice feces.

Food should not be handled more than necessary. The health of food handlers is obviously important. It is especially prepared foods, such as chopped meats, sausage, meat pies, and brawn that cause trouble. Such fussy and fingered foods are not necessary and are to be avoided.

It should be remembered that articles other than meat are sometimes infected, especially milk, cream, ice cream, potato salad—the list is long and comprehensive. Cleanliness and freshness are the watchwords.

Food infections are especially apt to take place from foodstuffs that have not been properly refrigerated. *B. enteritidis* may grow and multiply at temperatures as low as 10° C. Foods that have been handled, chopped, fixed or prepared some hours before the meal are most apt to give trouble; hence, the frequency with which food poisoning is associated with picnic lunches, fraternity dinners, and banquets.

Cooking is our great safeguard. These non-spore bearing bacilli are readily killed. The cooking must be thorough and should be recent, that is, just before serving. See page 749.

## BOTULISM

(Allantiasis)

Botulism is a specific intoxication caused by the toxin of the *Bacillus botulinus* (*Clostridium botulinum*). The bacillus grows in a great variety of foodstuffs, both of plant and animal origin, and produces its poison in the food before it is eaten. The name botulism has lost its original significance (botulus, a sausage).

Botulism stands alone as a type of food poisoning. It is well understood and is the only known instance in its class. The bacillus itself is essentially a saprophyte. Botulism further differs from the usual type of food poisoning in that the intoxication chiefly affects the central nervous system. Acute gastro-intestinal disturbances usually do not occur. There is no fever.

A complete history of the condition and a thorough review of the literature is found in Dickson's monograph.<sup>39</sup>

**Prevalence.**—Botulism has been recognized by German clinicians since 1735, when the first authenticated case was recorded. The outbreak which first attracted the attention of the medical profession occurred in 1793 in Wildbad in Württemberg, where 13 persons became ill and 6 died after eating sausage packed in the stomach of a hog, and which contained a great deal of blood. The number of cases reported in Germany are as follows:

From 1793 to 1820	76 cases	37 deaths
“ 1820 “ 1822	98 “	34 “
“ 1822 “ 1886	238 “	94 “
“ 1886 “ 1913	about 800 “	about 200 “

Dickson<sup>40</sup> was able to tabulate, during the twenty years prior to 1917, 22 outbreaks of botulism in the United States. Of these, 18 occurred on the Pacific Coast—17 in California and 1 in Oregon. These outbreaks involved 81 individuals, 55 of whom died—a mortality of 67.9 per cent. Since then, the outbreaks have been collected by Dr. Dwight L. Sisco, while working on the subject in my laboratory;<sup>41</sup> and tabulated on the next page.

The cause of botulism was demonstrated by van Ermengem<sup>42</sup> who studied a series of cases which occurred at Ellezelles, in Belgium, in 1895. In the first of these outbreaks, 23 persons became ill and 3

<sup>40</sup> J. A. M. A., Sept. 22, 1917, LXIX, p. 966.

<sup>41</sup> To this must be added several recent outbreaks due to canned spinach.

## OUTBREAKS OF BOTULISM IN THE UNITED STATES AS REPORTED IN THE LITERATURE SINCE 1917

Year	Reported by	Where Outbreak Occurred	Food Suspected	B. Botulinus Isolated From:	Number of Persons Who Ate the Suspected Food	Number of Persons Made Ill	Number of Deaths	Per Cent. Mortality Among Those Made Ill	Remarks
1916 <sup>1</sup>	Neylin and Mann								
1917 <sup>2</sup>	Rene Bine	Not stated	Cottage Cheese	Cheese	2	2	2	100.0	Evidence far from convincing. Probably not botulism.
1918 <sup>3</sup>	L. St. John Levy	Michigan	Apricot Butter	Not Isolated	8	8	6	75.0	Data very incomplete. Only questionably botulism.
1919 <sup>4</sup>	Grossman	New York City	String Beans	Not Isolated	1	1	0	0.0	Illness occurred after eating in a restaurant; string beans suspected. Symptoms remotely suggestive of botulism. Diagnosis purely clinical.
1919 <sup>5</sup>	Thom, Edmondson and Giltner	Boisc, Id.	Home Canned Asparagus	Asparagus	5	4	4	100.0	No information given relative to the one person who "escaped."
1919 <sup>6</sup>	Armstrong	Canton, O.	Ripe Olives	Olives	15	14	7	50.0	
1919 <sup>7</sup>	C. A. Jennings, R. W. Hauss & A. F. Jennings	Detroit, Mich.	Ripe Olives	Olives	8	7	5	71.5	
1919 <sup>8</sup>	D. L. Sisco	Java, Mont.	Stuffed Ripe Olives	Olives	7	7	5	71.5	At the time of this report two people were said to be recovering.
1919 <sup>9</sup>	D. L. Sisco	Spokane, Wash.	Home Canned Beets	Not Isolated	3	3	3	100.0	Both morphologically and culturally similar to B. botulinus isolated from beets, but it produced no toxin. Clinically typical.
1919 <sup>10</sup>	McCaskey	Indiana	Not Suspected	Not Isolated	7	7	4	56.8	All data fragmentary. Diagnosis entirely clinical.
1919 <sup>11</sup>	D. L. Sisco	Scottsbluff, Neb.	Home Canned Spinach	Not Isolated	2	2	2	100.0	Diagnosis entirely clinical.
1919 <sup>12</sup>	D. L. Sisco	Watertown (Ftine) New York	Home Canned Succotash	Not Isolated	7	7	5	71.5	Clinical diagnosis. B. botulinus not in the material examined.
1920 <sup>13</sup>	B. W. Fontaine	Memphis, Tenn.	Ripe Olives	Olives	7	7	7	100.0	
1920 <sup>14</sup>	D. L. Sisco	New York City	Ripe Olives	Olives	7	6	6	100.0

died after eating ham which had been preserved in brine. From portions of the ham and from the spleen and intestinal contents of one of the victims, van Ermengem succeeded in isolating a gram positive, spore-bearing anaërobic bacillus, to which he gave the name *Bacillus botulinus*. He found that infusions of the macerated ham, and bouillon cultures of *Bacillus botulinus*, produced the typical symptoms of botulism in guinea-pigs, rabbits, cats, pigeons and monkeys. The bacillus itself he believed to be a saprophyte, and the poisoning to be due to a toxin which is formed when it grows in food under anaërobic conditions.

Botulism is much more common in Europe than in this country. Savage states that not a single outbreak has come to light in England, Scotland or Wales. Botulism is a rare disease. The high mortality, the distressing symptoms and the relation to food have dramatic news value, and the disease has recently caused concern and alarm out of all proportion to its importance. A disease which, during a period of 22 years, has made only about 150 people ill and caused the death of 111 of these, among approximately 100 millions of people, cannot be compared in magnitude with tuberculosis and other public health problems.

Botulism presents no particular distribution as to sex, age, season, or social condition.

Botulism is one of the causes of forage poisoning in horses, and of limberneck in chickens and turkeys, and may also be responsible for various types of paralysis in domestic animals, including dogs.

**Symptoms.**—The symptoms usually appear from 18 to 36 hours after ingestion of the poisonous food. However, cases are on record in which the incubation period has been as short as 4 hours or as long as 6 days. The period of incubation probably depends upon the amount and virulence of the toxin ingested.

The earliest symptom is usually a peculiar indefinite indisposition, associated with a feeling of fatigue, sometimes headache and dizziness, and definite muscular weakness. When the period of incubation is short, the first symptoms may be gastric distress, nausea, vomiting and occasionally diarrhea. This makes the diagnosis questionable, for botulism differs from the common type of food poisoning, in that there are usually no indications of acute gastro-intestinal irritation. Constipation is an almost constant manifestation of the condition.

Disturbances of vision occur early. Scintillation and dimness of vision progress sometimes to blindness. The disturbances of vision are due to impairment of both the extrinsic and intrinsic muscles of the eye. The third cranial nerve is early involved, causing blepharoptosis, dilatation of the pupils, loss of reflex to light, and diplopia. Loss of accommodation soon becomes complete. Nystagmus, strabismus, and ver-

tigo and sometimes photophobia occur. The ophthalmoplegia is merely a phase of the more general paralysis, but may be conveniently separated, owing to the striking character of its manifestations.

Coincident with, or closely following, the onset of disturbances of vision, the patients complain of difficulty of swallowing and talking, and frequently there is a peculiar sensation of contraction of the throat. The mouth is dry and attacks of strangling occur. Thick, glairy mucus, with dryness of the throat leads to an ineffectual cough. The breath is offensive and fetid. Complete paralysis of peristalsis causes the stubborn constipation.

A striking feature is the progressive muscular weakness which in severe cases closely simulates paralysis. Incoördination of muscular movement is common. The *paralysis* is in a general way an ascending paralysis manifesting itself first in the intestines, perhaps due to involvement of the mesenteric plexus, then gradually passing upward, progressively involving higher centers, until the medulla is reached. The motor areas seem almost never to be involved, although in the recent Montana outbreak paralysis of the right arm and leg was observed.

The *loss of nervous tone* manifests itself in vague, indefinite indisposition, marked fatigue, dizziness, headache, restlessness, indefinite sensations of chilliness, incoördination and unsteadiness in walking with a tendency to a "steppage" gait, great muscular weakness and sometimes urinary incontinence. The ophthalmoplegia may be partly responsible for some of the above symptoms.

Botulism is characterized by an almost complete absence of sensory disturbances. It is unusual to suffer pain, and the mind remains clear.

Inhibition of many of the secretions, especially saliva, sweat, and tears, is an almost constant manifestation of botulism. Oliguria has been noted.

The pulse is usually rapid, and the temperature subnormal. Fever developing late in the poisoning indicates bronchopneumonia. Respiration at first is not impaired but later in the course of the illness disturbances of respiration become very severe. Difficult articulation and perhaps complete aphonia, accompanied by an inability to swallow, soon appear, due to paralysis of the laryngeal and pharyngeal muscles. Increasing difficulty in breathing, leading eventually to death due to paralysis of the respiratory center, brings the scene to a close.

The general appearance of the patient is distressing: the muscular weakness, the anxiety and utter helplessness, the difficulty in swallowing, the attacks of strangling, the struggle for breath, and the unsuccessful attempts to articulate constitute a clinical picture which once seen can never be forgotten.

The most characteristic symptoms seem to be dimness of vision, diplopia, palpebral ptosis, fatigue, progressive muscular weakness, difficult

articulation and swallowing, and respiratory paralysis. The clinical picture is essentially that of a bulbar paralysis, with the earliest symptoms indicating injury high up in the brain stem. The disease must be differentiated from other causes of bulbar paralysis and ophthalmoplegias, such as encephalitis lethargica, poliomyelitis, cerebrospinal syphilis; also poisoning from belladonna, gelsemium, hyoscyamus and methyl alcohol.

The duration varies greatly. Death may occur in 48 hours after eating the poisonous food; as a rule, it occurs in from 4 to 8 days, and few die after 10 days. Dickson reports one death on the 26th day. Death usually is due primarily to respiratory failure. Convalescence is extremely slow and tedious. The disturbances of vision and weakness may last for months.

The mortality of botulism has varied greatly in different outbreaks, depending upon the amount and virulence of the toxin. In certain instances it has been extremely high—in some 100 per cent.—but in others it has been correspondingly low. Wosnitzer<sup>43</sup> recorded a series of 59 cases of which only 4 died. In Kerner's series<sup>44</sup> of 159 cases, there were 84 deaths, a mortality of 52.8 per cent., and in Scholssberger's series<sup>45</sup> of 400 cases there were 150 deaths, a mortality of 37.5 per cent. The most complete collection of cases is that of Mayer,<sup>46</sup> in 1913, in which he reports 812 cases of which 365 were fatal, a mortality of 44.9 per cent.

**Pathology.**—The pathology of the disease has been but little studied. Wilbur and Ophuls<sup>47</sup> reported hyperemia of the viscera and widespread thromboses in the blood vessels of the meninges and brain. Dickson,<sup>48</sup> after a careful review of the literature as well as from his own experiments, concludes that thromboses in the blood vessels of various organs of the body are a characteristic lesion of the disease. The only constant finding on macroscopic examination of the bodies of victims of botulinus poisoning is the marked congestion of the central nervous system, and of the abdominal and thoracic viscera. Not infrequently there are multiple hemorrhages around the base of the brain and the upper part of the cord. The lungs are usually extremely hyperemic.

**The Bacillus.**—The *Bacillus botulinus* discovered by van Ermengem in 1895 is a large, slightly motile rod, 4 to 6 long, 0.9 to 1.2  $\mu$  thick.

It has slightly rounded ends; 4 to 8 flagellae, generally single; rarely occurs in filaments; has a large polar spore; stains readily, and is Gram-positive. The new name is *Clostridium botulinum*.

The bacillus grows well at room temperature, between 20° and 30° C., but also thrives at 37° C. Contrary to previous opinion, it may grow in the body. It is an anaërobe, but may grow under imperfect anaërobic conditions; also if in symbiosis with certain aërobic bacteria, such as a white *Sarcina* (van Ermengem) or with *B. subtilis* (Romer); and, according to Harrass and also Tarozzi, will grow in freshly prepared bouillon under aërobic conditions if a piece of sterile flesh or potato is placed on the bottom of the culture tube. The addition of glucose to the culture medium greatly increases its activity in growth and in toxin formation. In a medium consisting of one part sheep's brain and two parts water it grows well and produces an abundance of spores. The strains studied by van Ermengem produced practically no change in the appearance of milk, but von Hibler and others find that milk casein is precipitated and peptonized. It is strongly proteolytic, and a putrefactive odor is given off. Gas which is usually formed is due to the fermentation of sugars in the medium. The 21 cultures studied in my laboratory show minor differences in cultural characteristics; only ten of these strains produce toxin. Atoxic strains must be differentiated from *B. sporogenes*.

There are at least two distinct strains, A and B, which produce specific and heterologous toxins and antitoxins; that is, the antitoxin of strain A does not neutralize the toxin of strain B, and the antitoxin of strain B does not neutralize the toxin of strain A.

The habitat of *B. botulinus* in nature is not definitely known. It is assumed to be an intestinal and soil organism, like tetanus, the gas bacillus, and other anaërobes. Mrs. Burke<sup>49</sup> has recently thrown light upon the occurrence of *B. botulinus* in nature. In five different localities in central California she made 235 cultures from a wide range of material. Seven of the cultures, taken from bean plants, moldy hay, bush beans, cherries and spiders, contained *B. botulinus*. Some of these things were contaminated with the feces of insects and birds. Graham encountered *B. botulinus* in relatively large numbers in animal foods, including ensilage, oats, hay, corn fodder and bran, in Kentucky and Illinois. Such observations demonstrate the possible wide distribution of the organism and the fact that it may be present on fruits and vegetables before they are picked. It also suggests that insects or birds may act as carriers, a possibility which is rendered more probable by the discovery of *B. botulinus* in forage contaminated with chicken feces.

Evidence is increasing that *Bacillus botulinus* is associated with animal manure and that the spores are widely distributed in nature,

<sup>49</sup> *J. Bact.*, IV, 541, Sept., 1919.

in dirt and dust. They appear to be more abundant in some localities than in others.<sup>50</sup>

**Thermal Death Point of the Spore.**—To safeguard against botulism in canned foods, the thermal death point of the spore was determined in my laboratory by Weiss.<sup>51</sup> The various factors, such as age of the spore, number of spores, strain differences, hydrogen ion concentration, effect of desiccation, etc., which influenced the thermal death point were also determined.

Weiss found that suspended in water, the most resistant types require five hours at boiling temperature, 40 minutes at 105° C., 15

FIG. 75.—CURVE I, SHOWING THERMAL DEATH POINT OF *BACILLUS BOTULINUS*.

minutes at 110° C., and 6 minutes at 120° C. These represent bath temperatures and include the time necessary to heat the spore itself to the temperatures stated. Weiss further found that young spores are more resistant than old spores; that dry spores are much harder to kill than moist spores; and that acids, alkalies and various chemicals greatly diminish the thermal resistance.

**Toxin.**—The bacillus produces a soluble, true exotoxin<sup>52</sup> comparable in all respects to the poisons produced in cultures of diphtheria or tetanus. The botulinus toxin is the only one of the true toxins that

<sup>50</sup> Meyer, K. F.: The Distribution of the Spores of *B. Botulinus* in Nature. *Public Health Reports*, Jan. 7, 1921, Vol. XXXVI, No. 1, p. 4.

<sup>51</sup> *Jour. Infect. Dis.*, 28, 1, Jan. 1, 1921, p. 70.

<sup>52</sup> For definition of a true toxin, see page 553, *et seq.*

is poisonous when taken by the mouth. It is thus pathogenic for guinea-pigs, mice, and monkeys, as well as for man. One or two drops of a culture placed upon a piece of bread causes death in a few days. Toxins of diphtheria and tetanus are not poisonous when taken by the mouth.

The toxin is secreted by the bacillus when it grows upon a suitable medium, under anaërobic conditions. Some strains do not produce toxin, and the property may be lost after prolonged artificial cultivation. Toxin production takes place between 20° and 30° C., but best at 37° C.; this is contrary to our previous conception. It has always been believed that *B. botulinus* is strictly saprophytic and will not develop and produce its toxin in the body, the toxin being always preformed in food-stuffs, but the recent work of Orr<sup>53</sup> in my laboratory shows that guinea-pigs and mice may develop botulism when fed with large quantities of toxin-free spores. The significance of this observation to human botulism must await further study.

Botulinus toxin is exceedingly poisonous. It has been possible to obtain a toxin of which 0.000001 c.c. would kill a 250-gram guinea-pig in from 3 to 4 days.<sup>54</sup> In the Elzevelles outbreak,<sup>55</sup> about 200 grams of the poisonous ham were sufficient to cause the death of one of the patients: in the Darmstadt outbreak,<sup>56</sup> a piece of preserved duck the size of a walnut was sufficient to cause an illness which lasted for 8 weeks. In Dickson's series of cases, one patient died after "nibbling" a portion of a pod of the spoiled string beans, one died after tasting a small spoonful of the spoiled corn, and a third was ill after tasting a pod of beans which she did not swallow.

Strong toxin was produced by Dickson in pork and beef infusion, and also in media prepared from string beans, green corn; much less virulent toxins were obtained in media prepared from asparagus, artichokes, apricots, and crushed apricot stones. The most powerful poisons are produced in glucose broth. The toxin is not formed in brine containing over 8 per cent. of sodium chlorid. This is of practical importance in pickling foods.

Van Ermengem<sup>57</sup> showed that the toxin was destroyed by heating at 80° C. for one-half hour, and many later workers have verified this, showing in fact that there is a large margin of safety in such a procedure. Thom, Edmondson and Giltner<sup>58</sup> showed that the toxin of the Boisé strain is destroyed at some point between 70° C. and 73° C. by heating for 10 minutes. Orr<sup>59</sup> showed that the most resistant of

the ten strains of toxin studied by him is destroyed when exposed to 80° C. for two minutes, 72° C. for ten minutes, and 65° C. for 85 minutes. The toxins of most strains are killed at 65° C. in thirty minutes. Cooking therefore is a safeguard. The toxin in solution is very resistable to exposure to light and air. It is not affected by drying or putrefaction.

The toxin has a special affinity for the central nervous system; it is almost a pure neurotoxin. It also acts upon the blood vessels, causing dilatation, thrombi and hemorrhages in various portions of the body.

FIG. 76.—CURVE II, SHOWING RATE OF DESTRUCTION OF BOTULINUS TOXIN.

Van Ermengem<sup>60</sup> found that white mice, guinea-pigs, rabbits, cats, pigeons, and monkeys are susceptible to subcutaneous, intraperitoneal, and intravenous injection, and that white rats, dogs, chickens, frogs and fish are highly resistant. In his feeding experiments, he found that mice, guinea-pigs, and monkeys are especially susceptible, rabbits are less susceptible, and cats must be given enormous quantities of the toxin before they show any symptoms. He found that dogs, rats, and chickens are practically unaffected, the only result of feeding very large doses being vomiting, diarrhea and emaciation. It is surprising that van Ermengem failed to obtain positive results in his experiments with dogs and chickens, as Dickson and others have found that botulism may

<sup>60</sup>*Arch. Pharm.*, 1897, III, 213; *Z. Hyg. u. Infektionskrankh.*, 1897, XXXVI, 1; "Handbuch der nathegenen Mikroorganismen," Kolle u. Wassermann, Jena, 2nd ed., 1912, IV, 909.

cause limber neck in chickens and turkeys. Horses, goats and other animals are susceptible.

Every strain of *Bacillus botulinus* does not produce toxin.<sup>61</sup> Thus, Orr found only 10 of 21 strains to produce toxin. Furthermore, there are at least two distinct toxins—each of which produces a specific antitoxin.

**Antitoxin.**—A true antitoxin may be obtained by injecting increasing amounts into susceptible animals. Kempner first obtained the antitoxin in goats. It is now made by injecting horses. The botulinus antitoxin has both protective and curative virtues in experimental animals, even when given 24 hours after the ingestion of the poison, but before the onset of symptoms. For practical purposes at least two antitoxins must be on hand, one made by strain A, and the other by strain B.

Like other antitoxins, the botulinus antitoxin must be given very early if it is to be effective, and it is probable that, as in tetanus, it is too late when the symptoms of poisoning are established. The occurrence of limber neck in domestic fowl, if it develops after they have eaten refuse from the kitchen, should be sufficient reason for administering botulinus antitoxin to all persons who have eaten any of the suspected food. The presence and type of toxin in food can be determined in a few hours by injecting mice intraperitoneally. Some of the mice should be immunized with antitoxin Type A and some with Type B. Etherization delays intoxication; alcohol precipitates the toxin *in vitro* and in the stomach.

**Food Involved in Botulism.**—It was originally thought that *B. botulinus* would grow only in sausage or meat, but it is now known that the presence of animal protein is not necessary for its growth. In Europe, the foods involved in outbreaks have been mainly meats, such as sausage and ham, but in this country other foods have been involved, such as string beans, cottage cheese, corn, asparagus salad, spinach and ripe olives. Botulism has also been attributed to turkey, beef, chicken and fish.

Suspicion often falls upon the wrong food. The period of incubation is usually from 18 to 36 hours, and the first symptom may be nausea and vomiting. Several meals will have been taken between the time of eating the toxic food and the onset of initial symptoms. The food vomited is naturally accused. This mistake was made in the Detroit outbreak, where corn was suspected because it was found in the vomitus, whereas the trouble really came from ripe olives eaten the day before.

Most cases of botulism are caused by food that has received some preliminary treatment, as smoking, canning or pickling, and not in fresh food. Home packed foods have been especially responsible, for the reason that they are often a day or more old when put up, and the

<sup>61</sup> Non-toxic strains closely resemble *B. sporogenes*.

temperature of processing is frequently not sufficient to kill the botulinus spores. All the olive cases were due to ripe olives, put up in glass, and improperly processed.

Van Ermengem found that the outbreak in Ellezelles was caused by eating ham which had been preserved in brine. Smoked as well as pickled ham has been responsible. In Russia fish has conveyed the poison. Madsen also isolated *B. botulinus* from poisonous fish. A most interesting outbreak occurred in Darmstadt in 1904, caused by a salad prepared from home canned white beans.

Sausages are a frequent source of botulism in Germany. The sausages readily become infected and present ideal anaërobic conditions for the growth of the organism, especially as they are rarely refrigerated and frequently contain old and contaminated scraps. The disease is, therefore, frequently called sausage poisoning. Certain sausages, as, for example, the blood sausage and the liver sausage prepared in Württemberg and Baden, are especially apt to be infected. Venison and old roasts have also produced the intoxication.

No reliance can be placed upon odor, taste or appearance to detect the toxin of botulism in food. It is true that in many instances a history is obtained that the responsible food looked spoiled, tasted wrong, or smelled tainted. Experts can detect the peculiar butyric acid smell of cultures of botulinus, but we found in my laboratory that some strains produce little or no odor. A safe rule is not to eat food that is soft, mushy, and shows gas with a spoiled or putrefactive odor. Canned food that shows gas formation or other evidence of spoilage should not be eaten, especially if home processed. A very small amount of the toxin-containing food is sufficient to cause symptoms and death. Merely tasting the contents, or just "nibbling" the food has been fatal.

**Prevention.**—The prevention of botulism consists in greater care and cleanliness in the handling and preservation of nitrogenous food-stuffs. The bacillus will grow and produce toxin only in foods containing protein. There is no danger of botulism in fresh food. In all instances, the trouble comes from food that has been pickled, canned or preserved in some way, such as pickled ham, home processed beans, sausages, etc. Home canned foods are often at fault. It is therefore important to teach safe methods of home canning, especially the importance of putting up only fresh and clean food, heated sufficiently to kill the spores—120° C. for 10 minutes. Canned foods should be processed at a temperature sufficient to kill botulinus spores, and to render the contents of the can sterile. The cans should be tight.

Food that is allowed to stand around after cooking allows bacterial growth, unless kept in the ice box, with a temperature at or near freezing. The importance of proper refrigeration to prevent botulism, as well as other bacterial contamination, is evident.

Cooking is a safeguard, but it must be thorough and sufficient to kill the toxin—80° C. for 10 minutes. If the food is kept at ordinary temperatures after cooking, botulinus and other organisms may grow and may cause trouble. Toxin may re-form in cooked food allowed to stand 24 hours at room temperature. Home canned goods, or any other processed goods, should be again cooked just before serving. Food preserved in a brine of 8 per cent. or greater is safe, for the toxin does not form in salt solution of this concentration. A syrup of at least 50 per cent. glucose has been found necessary to inhibit growth.

No reliance should be placed upon odor, taste or appearance of the food; on the other hand, no food, whether canned or processed in any other way, should be consumed if it shows evidence of spoilage. Education, therefore, with emphasis upon proper methods of handling, preserving, canning, washing and cooking food, is important.

The occurrence of limber neck in domestic fowl, if it has developed after they have eaten refuse from the kitchen, may be an indication for the prophylactic administration of the botulinus antitoxin to all persons who have eaten the suspected food.

When a case of botulism occurs, other persons who may have eaten the suspected food should receive a prophylactic dose of botulinus antitoxin; both strains A and B should be used. The serum is of little avail after symptoms have begun.

## DECOMPOSED FOODS

Decomposition is defined as natural decay. In this sense all organic substances, both animal and vegetable, living or dead, are decomposed, for decomposition and recomposition occur as a constant feature of life's processes. At the moment of death recomposition ceases, while decomposition continues. In one sense the hardest rocks decompose or disintegrate; bicarbonate of soda decomposes in the presence of an acid, and many substances decompose in the presence of oxygen, especially when heated. In other words, while decomposition is usually the result of bacterial activity in organic substances, it may also take place as the result of physical, chemical, or electrical agencies. The word "decomposition" is not used in this technical sense in the Pure Food and Drugs Act; there it has the meaning of the word used in ordinary, every-day parlance. Just where technical decomposition ceases and objectionable decomposition begins is often difficult to determine. Decomposition may be objectionable either to the senses or to health. We purposely permit many of our foods to decompose before they are used. Thus, meats hang three days or longer in order to render them

more tender and to improve their flavors. During this time decomposition takes place with the production of acids. Some persons prefer meats when highly decomposed or gamy. Bread, cheese, butter, buttermilk, sauerkraut, vinegar, cider, and many other foods are products of decomposition. The line must, therefore, be drawn between decomposition that is objectionable and decomposition that is technical. It is difficult to draw the line at decomposition that is objectionable to the senses, for a cheese regarded as a delicacy by one person may be highly objectionable to another. The principal point, then, for consideration is the decomposition that is harmful to health.

**Fermentation and Putrefaction.**—The question is further complicated when we consider that there are very many kinds of decomposition. Two main groups are recognized: (1) fermentative decomposition, and (2) putrefactive decomposition.

Fermentation refers to the breaking down of carbohydrates with the formation of acids (lactic, acetic, butyric), alcohol, carbon dioxide, etc.

*Putrefaction* (putrere, to be rotten) is literally a process of rotting or offensive decay. Putrefaction is generally restricted to include only those processes of protein disintegration which give rise to foul-smelling products. For practical purposes, it consists of the decomposition of organic matter, usually protein in character, due to bacterial action.

Pasteur first pointed out that putrefaction is essentially an anaërobic process. This has since been abundantly confirmed. Rettger insists that putrefaction is the work of certain obligate anaërobes, which are able to initiate and carry on the decomposition of native protein. *B. putrificus*, *B. edematis maligni*, and *B. anthracis symptomatici* are the best examples. *B. tetani* does not have a place in this group. *B. perfringens*, the gas bacillus of Welch, has only a limited if any proteolytic action. Certain aërobes, such as the proteus family, the colon group, and the subtilis group, also play a part, although they cannot initiate changes in protein.<sup>62</sup>

The end products of putrefaction are ammonia, nitrates, carbon dioxide, sulphureted hydrogen, methane, etc., all simple, stable, inorganic compounds which, in ordinary concentration, are not poisonous. It is then the intermediate cleavage products of putrefaction and the end products of fermentation that may be poisonous. The question of decomposition is still further complicated by the fact that there are very many different kinds of fermentation and of putrefaction. Each particular microorganism breaks down organic matter in a specific and limited sense. Ordinarily these processes result from a combination of bacterial action (symbiosis), in which aërobic and anaërobic organisms

<sup>62</sup> Bienstock, *Arch. of Hyg.*, XXXI, p. 335, 1889, and XXXIX, p. 390, 1901; also Rettger, *Journ. Biol. Chem.*, II, p. 71, 1906, and IV, p. 5, 1908.

each play a part. As a rule, putrefaction does not take place in the presence of fermentation. In this sense carbohydrates protect nitrogenous matter.

**Putrefactive Changes in Proteins.**—To understand clearly the degradation changes in proteins as a result of putrefaction it is necessary to give a brief account of the composition of the animal proteins and their simpler cleavage products.

The proteins are highly complex compounds of C, H, O, N and S, belonging for the most part to the colloids. The protein molecule is a very large one. Some fifty or so natural proteins are known, occurring in both animals and plants, and they are classified according to their origin, solubility in solvents such as water, saline solutions and alcohol, coagulability on heating and other physical characters.

The work of Emil Fischer and his pupils has confirmed and elaborated the theory originally propounded by Hofmeister, that the protein molecule is built up of a series of amino-acids forming a class of products which have been designated the polypeptids by Fischer. Such polypeptids form the essential part of the structure of the protein molecule, but it may contain other groups, such as phosphoric acid and possibly also carbohydrates and lipoids.

The amino-acids are bodies in which a  $\text{NH}_2$  group (the amino group) is substituted for a hydrogen atom of the carbon group nearest the acid radical. For example, acetic acid is a simple, fatty acid with the formula  $\text{CH}_3\text{—COOH}$ , while  $\text{CH}_2\text{NH}_2\text{—COOH}$  is amino-acetic acid or glycocoll. The aromatic amino-acids are those in which amino-acids are united to the benzene ring. Tyrosin belongs to this group. The general formula of the monoamino acids may be stated as  $\text{R—CH}$   $\begin{matrix} \nearrow \text{COOH} \\ \searrow \text{NH}_2 \end{matrix}$

where R may be of very simple or very complicated structure; for example, simple chains as in leucin, members of the aromatic series as in tyrosin or tryptophan or sulphur-containing bodies.

In the diamino-acids two hydrogen atoms are replaced by  $\text{NH}_2$  groups and these have the general formula  $\text{R—C}$   $\begin{matrix} \nearrow \text{NH}_2 \\ \searrow \text{NH}_2 \end{matrix}$   $\text{—COOH}$ . Lysin and arginin belong to this group.

Under the influence of chemical agencies, such as acids or alkalis, physical agencies, such as superheated steam, the action of digestive or other ferments or the activities of bacteria, the protein molecule is decomposed and various cleavage products form. These substances may be classed as primary cleavage products, i. e., those which exist as radicals within the molecule, or as secondary products, i. e., those not existing preformed in the molecule but formed by transformation of the primary products.

"When the protein molecule is broken down in the laboratory by processes similar to those brought about by the digestive enzymes which occur in the alimentary canal, the essential change is due to what is called hydrolysis: that is, the molecule unites with the water and then breaks up into smaller molecules. The first cleavage products, which are called proteoses, retain many of the characters of the original protein; and the same is true, though to a less degree, of the peptones, which come next in order of formation. The peptones in their turn are decomposed into short linkages of amino-acids which are called polypeptids, and finally the individual amino-acids are obtained separated from each other" (Halliburton, 1916).

It is important to realize that whatever method is used to decompose the protein molecule the process goes through all these stages and approximately quantitatively as well as qualitatively. Different agencies, however, carry the process to different stages and the characteristic chemical products brought about by putrefactive bacteria are due to their carrying the processes further and causing extensive secondary cleavage changes.

The conversions into proteoses, peptones and amino-acids are therefore changes which are common to all methods by which the protein molecule is decomposed, and chief interest centers upon the further changes in the amino-acids brought about by the putrefactive bacteria. Bacteria (and fungi) are peculiar in being able to break down the amino-acids into bases and acids which, in general, have not been demonstrated as products of the metabolism of animals and the higher plants.

As long ago as 1902 Czapek, and also Emmerling, pointed out that the amino-acids furnish bacteria with abundant and available nutritive material. The amino-acids are non-toxic bodies and include substances such as glycine (amino-acetic acid), alanine (aminopropionic acid), leucine (iso-butyl- $\alpha$ -amino-acetic acid), tyrosine, cystine, aspartic acid, glutamic acid, histidine and tryptophan.

The secondary degradation products which result include bodies such as indole, skatole, skatolcarboxylic acid, skatolacetic acid, phenylpropionic acid, phenylacetic acid, *p*-cresol and phenol. In addition a number of simple bodies, such as ammonia, methane, carbon dioxide, sulphureted hydrogen, hydrogen, etc., are formed as end products.

The precise chemical bodies which will be formed will depend upon a number of factors, such as the character of the bacteria concerned, the conditions of growth (especially as regards the presence or absence of oxygen), the available sources of nutriment other than the amino-acids, the temperature and the stage of the process.

Hopkins and Cole (1903), for example, studied the changes produced in chemically pure tryptophan by putrefaction. They obtained

indol, skatol, and skatolcarbonic acid by the action of aerobic bacteria and skatolacetic acid with anaerobic organisms, in this way showing that the tryptophan radical is the precursor of these substances in putrefaction.

In the same way tyrosin is the precursor of phenol, paracresol, para-oxyphenylacetic acid and other bodies.

Most, if not all, of the sulphur in the protein molecule is contained in the amino-acid cystin and the offensive sulphur-containing bodies, such as hydrogen sulphid, methyl mercaptan ( $\text{CH}_3\text{SH}$ ) and ethyl mercaptan, produced during putrefaction are due to the breaking down of this amino-acid.

In addition to these numerous products a very definite group of bodies, chemically of the nature of amines, are formed in the later stages of putrefaction, and to these bodies, owing to the toxicity possessed by some of them, the very greatest importance has been attached as a cause of bacterial food poisoning.

A very characteristic action of putrefactive bacteria generally is their power to split off carbon dioxid from the carboxyl ( $\text{COOH}$ ) group of the amino-acids with the production of amines according to the following equation:

In this way a whole series of bodies is formed which include the ptomains of Selmi and Brieger and other bases, some of which were claimed to exert a poisonous action on man and animals. This decarboxylation of amino-acids seems to be a general reaction of a good many putrefactive organisms.

As examples of such changes it may be mentioned that diaminovaleric acid is converted into putrescin, diaminocaproic acid (lysin) into cadaverin, and tyrosin into tyramin. In the same way the poisonous and probably important body B-imidazoylethylamin (histamin) is the amine of histidin. The decarboxylation of amino-acids is not necessarily accompanied by a putrefactive odor or other obvious signs of bacterial action.

**“Ptomain” Poisoning.**—Ptomains are secondary cleavage products of protein putrefaction. Vaughan defines a ptomain as an organic chemical compound, basic in character, and formed by the action of bacteria on nitrogenous matter. On account of their basic properties ptomains give some of the reactions of the vegetable alkaloids and have, therefore, been called putrefactive alkaloids. They are sometimes called “animal” alkaloids, but this is a misnomer, for they also are formed in the putrefaction of vegetable protein.

The term “leukomain” is used to cover the same or similar basic substances which result from tissue metabolism within the body; that

is, leukomains are produced in the living body, ptomains in dead organic matter.

The word "ptomain" was coined by the Italian toxicologist Selmi, in 1870, from *ptoma*, a corpse. He used the term to describe basic poisonous products analogous to the familiar alkaloids of plant origin. The further exploitation of the expressive word "ptomain" was largely the outcome of studies by Gautier in 1872, who also introduced the term "leukomains."

The great majority of ptomains are not poisonous or less toxic than the corresponding ammonia compound. Ptomains include substances which are chemically very different. The classification is not a scientific one, and is gradually being abandoned. In fact, it is known that cases of so-called ptomain poisoning are really infections with microorganisms belonging to the Gaertner bacilli.

Chemically, ptomains are ammonia substitution compounds; two-thirds of them contain only carbon, hydrogen, and nitrogen. Those having oxygen in their composition are the more poisonous. Most ptomains are inert or are no more poisonous than the corresponding ammonia salts. In composition they show a predominance of the amin radicle ( $\text{NH}_2$ ). Of the bases containing oxygen, most of them are trimethylamins [ $(\text{CH}_3)_3\text{N}$ ]. It was Brieger who pointed out that a certain quantity of oxygen is necessary for the formation of poisonous bases. These poisonous bases appear about the seventh day of putrefaction and then disappear.

It is important to remember that ptomains, in sharp contradistinction to toxins, are non-specific, that is, they are not the products of intracellular metabolism characteristic of the microorganisms which produce them. They are merely degradation products of the protein molecule and are elaborated by all bacteria that are capable of producing this degree of protein cleavage when grown on suitable nutrient medium and under favorable conditions of growth. They may be produced by bacteria which possess no pathogenic power, while on the other hand highly pathogenic bacteria which are not active in attacking protein may produce little or no ptomains.

The term "ptomain poisoning" is a misnomer. A study of this subject for over three years has convinced me that there is no such thing. Savage states that the term "ptomain poisoning" is clearly incorrect, and Jordan states that "ptomain poisoning" is a refuge from etiologic uncertainty. Vaughan agrees with Jordan and Savage that the term "ptomain poisoning" is incorrect and should not be applied to food poisoning. Novy states that "the rather popular expression 'ptomain poisoning' is a survival of the period when it was believed that bacteria produced their injurious effects by means of basic or alkaloid-like products. Long ago the importance of ptomains disap-

peared, due in the first place to the discovery of toxins, and in the second place to the fact that these substances are not secondary products of protein cleavage." Chapin states that "ptomain poisoning" is a good term to forget. Vaughan, in 1895, detected in poisonous cheese an active agent to which he gave the name tyrotoxicon. However, he afterwards admitted that this is not the subject most commonly found in poisonous cheese, although the names tyrotoxicon and ptomain poisoning remain in popular parlance. Even the poisonous ptomains are toxic only when injected into animals and not when given by the mouth. The symptoms produced have no resemblance to cases of food poisoning.

It is not *decomposed* but *infected* food that may be dangerous.

Owing to the importance which is still attached by some to these bodies and their historical interest, particulars of a few are given. See Vaughan and Novy's book, *Cellular Toxins* (1903).

*Methylamin*,  $\text{CH}_3\text{NH}_2$ .—This is the simplest amin and has been obtained from decomposing herring, haddock and other fish. It does not possess any toxic action and very similar remarks apply to di- and trimethylamin and to ethylamin.

*Sepsin*.—The best known poison which has been isolated in an approximately pure state from decomposing nitrogenous material is sepsin. Much work has been done upon this substance by Schmiedeberg and recently by Faust, who obtained sepsin in a purified state in sufficient quantities carefully to study its action and composition. Faust obtained the crystals from putrefied yeast and blood; 25 milligrams of the sulphate introduced intravenously will kill a large dog in two hours.

Sepsin has the following chemical structure:

Sepsin is very unstable. It is rendered inactive at  $60^\circ \text{C}$ . for a short time, and is readily converted into cadaverin or pentamethylene-diamin. The chemical structure of cadaverin is:

*Cadaverin* is one of the best known of the ptomain group. Its presence indicates that the putrefactive process at one time contained sepsin which, by reduction, has been changed into cadaverin.

*Putrescin* is another diamin, which almost invariably occurs together

with cadaverin, to which it is closely related. It was first described by Brieger in 1885, and has been obtained from putrefying internal human organs, herring, mussels, etc. It is recognizable on the fourth day of putrefaction, and appreciable quantities appear by the eleventh day. It is still present after two or three weeks. Baumann in 1888 showed the rational formula to be:

Putrescin is a homolog of cadaverin and appears in putrefaction before that substance.

Van Slyke and Hart (1903) found a little putrescin in ordinary Cheddar cheese. Once formed putrescin and cadaverin appear to be very resistant to bacterial action.

Putrescin and cadaverin are of interest because they have been found in the intestine, derived from the putrefactive decomposition of proteins, and sometimes in the urine in cystinuria. They are said to have some physiological properties, setting up, according to Behring, poisonous symptoms in mice, rabbits and guinea-pigs. Udránszky and Beauman, however, failed to obtain any evidence of intestinal irritation when dogs were fed with enormous doses of cadaverin.

The cholin group of ptomains includes cholin, neurin, muscarin and betain and is of more interest.

*Cholin* is a normal constituent of every cell, forming the nitrogenous portion of the lecithin molecule. It is only very moderately toxic, but the closely related neurin into which it may be transformed is highly poisonous. It has been suggested that one form of food intoxication is due to the cholin, obtained from the lecithin in the food, being converted in the gastro-intestinal tract into neurin. While cholin in itself is not very toxic, Hunt has shown that acetylcholin is one hundred thousand times more poisonous. Cholin is a base widely distributed in nature; it is found in the yolk of eggs, in bile, brain substance, fat, seeds, and other substances. It can also be prepared from pure lecithin, which is a fatty body normally present in brain substance, yolk of eggs, and perhaps all cells. The lecithin may be readily decomposed by bacterial action perhaps to cholin and cholin salts. While acetylcholin has never been demonstrated in food, it is possible that this or similar poisons may be produced in decomposing foodstuffs.

Brieger obtained neurin in the putrefaction products of horse, beef and human blood after five to six days' action in summer.

*Muscarin* was obtained, accompanied by cholin, by Schmiedeberg and Koppe from poisonous mushrooms.

Both *neurin* and *muscarin* are extremely poisonous and very similar in their action. Subcutaneous injection of but 1 to 3 mg. of muscarin in man produces salivation, rapid pulse, reddening of the face, weakness, depression, profuse sweating, vomiting and diarrhea. Neurin acts very similarly. "The toxicity of these substances is so great that not a large amount would need to be formed by oxidation of cholin to produce severe symptoms, although it is not known that this occurs actually in the body. When introduced by the mouth, the lethal dose of neurin is ten times as great as when injected subcutaneously, indicating that chemical changes in the gastro-intestinal tract offer some protection against intoxication by these substances when taken in tainted food. Cholin, although by no means so poisonous as neurin, has a similar action when administered in sufficiently large doses. According to Brieger it is about one-tenth to one-twentieth as toxic as neurin" (Wells, Chemical Pathology).

*Mytilotoxin* is chiefly of interest in that it is said to be the specific poison in connection with mussel poisoning and was obtained by Brieger in 1885 from toxic mussels. He was, however, unable to obtain it from ordinary mussels which were allowed to putrefy for sixteen days. According to Brieger it produces all the characteristic effects seen in mussel poisoning. Its connection with mussel poisoning is considered on page 844.

The more the question of ptomaines is studied the less do they appear concerned in cases of food poisons. It is now clear that most, if not all, cases of so-called ptomain poisoning are nothing more nor less than acute infections with *B. enteritidis*, *B. cholerae suis*, and other microorganisms belonging to this group.

## ADULTERATION OF FOOD

Adulteration of food consists of a large number of practices, some of which are fraudulent, others technical in nature. Some forms of adulteration are injurious to health, but for the most part they have an economic rather than a sanitary significance. Foods may be adulterated in a variety of ways: by the removal of nutritive substances; by the addition of injurious substances; by the fraudulent substitution of cheaper articles; by misbranding; or by the sale of food that is filthy, decomposed or putrid.

Prior to the passage of the Pure Food and Drugs Act in 1906 a very large percentage of the food sold in the United States was found to be "adulterated" in one way or another. Thus, at the Agricultural Experiment Station in Kentucky 40 per cent. of 727 samples were adulterated; at the Connecticut Agricultural Experiment Station 41.5 per

cent. of 574 samples of spices were found adulterated, and over 25 per cent. of coffee samples were adulterated (1899).<sup>63</sup>

Among the common adulterations may be mentioned the following: cotton-seed oil is sold as olive oil; honey may contain glucose; cocoa and chocolate are frequently mixed with both starch and sugar; coffee is extensively adulterated with caramel, pea-meal, chickory, and saccharose extracts; lard is mixed with cheaper fats or cotton-seed oil; saccharin is substituted for cane sugar; cereals give bulk and weight to sausages; gypsum or bran is added to flour; barium sulphate to powdered sugar, flour or turmeric or corn meal to mustard. Oleomargarin is sold as butter; distilled and colored vinegar is sold as cider vinegar; ground spices are adulterated with coconut shells, rice, flour, and ashes; water, sugar, and tartaric is sold as lemonade; wines and liquors are sometimes adulterated with alum, baryta, caustic lime, salicylic acid, wood alcohol, and hematoxylin. Terra alba, kaolin, and various pigments are sometimes added to candies; gum drops are largely made with petroleum paraffin products; much of the maple sugar formerly sold was made from glucose and coloring matters.

**Definitions.**—A food is considered adulterated in accordance with the Food and Drugs Act of June 30, 1906: (1) "If any substance has been mixed and packed with it so as to reduce or lower or injuriously affect its quality or strength." This is the simplest form of adulteration, and a good example is the addition of water to milk. Cocoa shells are sometimes mixed with cocoa or chocolate. Glucose and caramel are added to maple sugar; talc to flour.

(2) "If any substance has been substituted wholly or in part for the article." As illustrations we have the substitution of cotton-seed oil or corn oil for olive oil; glucose or saccharin for sugar; cereals, which cost much less than meat, in sausage. Apple cores and parings are frequently used as a substitute for currants and other fruits in jellies.

Saccharin or ortho-benzo-sulphamid,  $C_6H_4 \begin{array}{l} \diagup CO \\ \diagdown SO_2 \end{array} \rangle NH$ , is made

from toluene. It is several hundred times sweeter than sugar and comparatively cheap. It has, therefore, been used as a substitute for sugar as a sweetening agent in the inferior qualities of ginger ale, and to some

<sup>63</sup> In Massachusetts the State Board of Health began to examine foods for adulteration in 1883. It was then found that between 60 and 70 per cent. of all foods examined were adulterated. As a result of official surveillance the percentages fell in a few years to, approximately, 15 per cent. and have remained between 10 and 20 per cent. since. This does not mean that from 10 to 20 per cent. of all foods found on the market are adulterated, for, to a great extent, samples are collected from suspicious sources, so that the ratio of adulteration of food analyzed in the laboratory is higher than that of the same foods sold on the market.

extent in canned corn, peas, etc., as well as in candies and other articles. Saccharin is a chemical obtained from coal tar and is without food value; it is not entirely harmless. The Referee Board reports that "the continued use of saccharin for a long time in quantities over 0.3 of a gram per day is liable to impair digestion; and the addition of saccharin as a substitute for cane sugar reduces the food value of the sweetened product and hence lowers its quality." Saccharin-containing foods are therefore regarded as adulterated within the meaning of the Food and Drugs Act.

(3) "If any valuable constituent of the article has been wholly or in part abstracted." Skimming milk is a good illustration of this part of the law, or the abstraction of cocoa butter from chocolate. There is, however, no objection to abstracting valuable or nutritive substances provided the label properly announces the facts; thus, skimmed milk or cocoa are legitimate foods. So also the caffein may be taken out of coffee and sold as caffein-free coffee. The essential oils are sometimes extracted from cloves or other spices, which are subsequently ground and used as an adulterant with unextracted spice.

(4) "If it is mixed, colored, powdered, coated, or stained in any manner whereby damage or inferiority is concealed." This is a very frequent form of adulteration, and, as a rule, is undesirable and sometimes injurious. Substances used to color foods are usually considered in three classes: (1) mineral dyes, (2) vegetable dyes, (3) anilin or coal-tar dyes. The principal *mineral dyes* are: copper sulphate, oxid of iron, and potassium nitrate. Copper sulphate is used to give a green color to peas, pickles, and similar foods. The copper probably unites with the albuminous matter to form new compounds which have a bright green sickly color. The oxid of iron and also sulphites are used upon meat to give it a red color; potassium nitrate will also give a bright red color to meat. Many *vegetable dyes* are used, such as annatto (the juice of the *Bixa orellana*, a South American tree), which is used to color butter. Carrot juice is also used; turmeric in mustard; and logwood in wines. The *coal-tar dyes* have largely replaced the vegetable and mineral pigments in foods, on account of their brilliant color and cheapness. They are used in sausages, confectionery, jellies and jams, meats, flavoring extracts, etc.

The artificial coloring of food is a false standard and serves no useful purpose. When the coloring matter is used to conceal damage or inferiority the practice is indefensible, as when spoiled meats are made to look bright red and fresh, or when oleomargarin is colored in order to imitate butter and sold as such. Flour may be bleached with nitrogen peroxid, thus giving an inferior grade the appearance of first quality flour. The  $\text{NO}_2$  is produced by electric action and nitrites in appreciable quantities remain in the flour. Fruits are bleached by ex-

posure to sulphur fumes, which leaves objectionable sulphur compounds. Candies and chocolate are often coated with gum benzoin or shellac.

(5) "If it contains any poisonous or other added deleterious ingredient which may render such article injurious to health." This section of the law is intended to include adulterants, such as formaldehyd, sulphites, arsenic, hydrofluoric acid, lead, salicylic acid, borax and boracic acid, as well as any other injurious substance. Most of the storm center of the opposition to the Pure Food Law is centered around this paragraph, owing to the difficulty of deciding in certain instances whether small amounts of benzoic acid or benzoates, boric acid or borates, are injurious to health or not. These substances are discussed more in detail under chemical preservatives.
